Series Editors

Charles W. Finkl, Department of Geosciences, Florida Atlantic University, Boca Raton, FL,
USA

Rhodes W. Fairbridge, New York, NY, USA

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists. These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. Most volumes are also available online. **Accepted** for inclusion in Scopus.

We dedicate the Encyclopedia of Mathematical Geosciences to two scientists: John Cedric Griffiths and William Christian Krumbein, who inspired the four of us and were directly involved in the creation of the field of mathematical geoscience. These two scientists symbolize our intention for the Encyclopedia of Mathematical Geosciences to connect the basic and applied divisions of the mathematical geosciences.

William Christian Krumbein (1902–1979) was a founding officer of the Association. Born at Beaver Falls, Pennsylvania, in January 1902, Krumbein attended the University of Chicago, receiving the degree of bachelor of philosophy in business administration in 1926, an MS in geology in 1930, and a PhD in geology in 1932. He taught at the University of Chicago from 1933 to 1942, advancing from instructor to associate professor. During World War II, from 1942 until 1945, he served in Washington, D.C. with the Beach Erosion Board of the U.S. Army Corps of Engineers. Following a short stint with Gulf Research and Development Company, immediately after the end of the war, he joined Northwestern University in 1946, serving there until mandatory retirement in 1970. He was named the William Deering Professor of Geological Sciences in 1960. Krumbein died on August 18, 1979, a few months after Syracuse University had awarded him a DSc (honoris causa). At his memorial service, former Northwestern colleague Larry Sloss said of Krumbein “that by constitutionally rejecting conventional wisdom, he continually pursued innovative methods whereby the natural phenomena of geology could be

expressed with mathematical rigor.” IAMG instituted the William Christian Krumbein Medal. This award was fittingly named for William C. Krumbein. He is considered one of the fathers of the subject.

John Cedric Griffiths (1912–1992), formerly Professor of Petrography at the Pennsylvania State University, was the first recipient of the IAMG’s Krumbein Medal in 1976. Like Krumbein, Griffiths remains well known as a pioneer of introducing quantitative methods across a wide spectrum of geological and economic problems. Born in Llanelli, Carmarthenshire, Wales, he graduated in petrology from the Universities of Wales and London prior to working for a petroleum company in Trinidad for 7 years. In June 1987, he retired after 40 years of teaching in the Department of Mineralogy and Petrology at the Pennsylvania State faculty. He directed more than 50 MSc and PhD students. From his classes, students learned the communality of scientific problems across different disciplines including industrial engineering, computer science, and psychology. During 1967–1968, he was the first Distinguished Visiting Lecturer at Kansas University in a program instigated by Professor Daniel Merriam. In addition to his well-known 1967 textbook Scientific Method in Analysis of Sediments, the scientific literature has been greatly enriched by his many articles. His work on unit regional values received international acclaim. Professor Griffith’s scientific distinction, coupled with his wit and lively often provocative oral presentations, have stimulated everyone lucky enough to have experienced them.

Foreword

It is a great honor for me to be invited to contribute this foreword to what is in so many ways an outstanding and impressive work. Dr. Sagar and his team are to be congratulated on bringing together such a complete and comprehensive reference work that will be invaluable to students, researchers, and educators for years to come.

Many people who are not already aware of the progress that has been made in the mathematical geosciences in the past few decades may wonder about the existence of such a field at the intersection between mathematics and the geosciences. The natural world often appears random and unpredictable, and thus very unlike the pure logic and beautiful symmetries of mathematics. To be sure, there are examples of something approaching purity and simplicity in the natural world: one thinks of the sine-generated curves of river meanders, the almost-perfect circles of craters, the elegant geometry of some periglacial features such as frost-wedge polygons, or the statistics of stream networks. It was features such as these that attracted my interest many years ago when I found myself enrolled as a PhD student working under a karst geomorphologist (Derek Ford) after a conventional background in undergraduate physics, where the idea that the world can be reduced to a few simple principles has dominated science for centuries.

At the opposite extreme, the geosciences have provided a rich set of applications for the mathematics of disorder and chaos. Many of Mandelbrot's initial examples of his developing mathematics of fractals were provided by the geosciences, including the geometry of shorelines. Moreover, some simple discoveries in the geosciences, such as the scaling laws and the laws of stream number, can be attributed to nothing more than the asymptotic result of randomness.

In a way, history has brought us full circle in the increasing use of artificial intelligence and machine learning in the geosciences. Thoroughly grounded in data science and in the fourth-paradigm mantra "let the data speak for themselves," these methods abandon any semblance of theory or generalizability in the search for algorithms that support searches and provide predictions based in complexity. While Occam's Razor and the traditional scientific search for simplicity may have largely failed to provide understanding and explanation in the geosciences, these methods are at least capable of revealing similarities and supporting an early, hypothesis-generating phase of a research project.

Before we go too far into data science, however, it is worth remembering the famous saying of Korzybski (1933): "The map is not the territory," that is, what the map or the data are trying to capture is no more than a representation of reality, and will be at best only an approximation, generalization, abstraction, or interpretation. The interpretations drawn from data, whether through statistical analysis or machine learning, will always be subject to the uncertainties that must be present in the data, along with other uncertainties that result from the use of imperfect models, and there will always be a danger that conclusions tell us more about those uncertainties than about reality.

In recent years, many branches of science have been the subject of inquiries into ethics. This may have begun with concerns about reproducibility and replicability in experimental psychology (NASEM 2019), and it grew further during the civil unrest in the USA in 2020 with the call to improve diversity, equity, and inclusion. Ethical issues arise in many areas of the geosciences, and more broadly in the social and environmental sciences. Individual privacy and surveillance often feature strongly in debates over ethics, but many other issues can be regarded as problems

of ethics (AAG 2022). They include making inappropriate or biased inferences from data, ignoring the presence of uncertainty in findings, or unwarranted generalization across space or in time. While none of the entries in the encyclopedia address ethical issues exclusively, and there are none on replicability or diversity, many of them provide a context for further discussion of ethics in specific areas, and perhaps future editions of the encyclopedia might include more on social issues such as these.

Anyone reviewing the encyclopedia and its many entries will wonder what it is that is different about the mathematics that is useful in the geosciences, and similarly about the statistical and computational methods, and the methods of data science. They might wonder what new developments in each of these areas have originated in the mathematical geosciences and perhaps spread into other fields. There are several examples of this in the encyclopedia: the article on Geographically Weighted Regression, which is entirely driven by the need for a relaxed form of replicability in order to deal with the essential spatial heterogeneity of the Earth's surface; and the entire field of geostatistics, which arose because of the necessity of dealing with geospatial data that exhibit spatial dependence, or regionalized variables in the terminology of Matheron. In inferential statistics, it is clear that the simple model, developed by Fisher and others in order to make conclusions about populations from samples drawn randomly and independently from that population, requires special methods to deal with samples in the geosciences that may be far from independent, and often represent an entire population rather than a sample from it.

This is an exciting time for the mathematical geosciences: new data streams are coming online, at finer and finer temporal and spatial resolution; new methods are emerging in machine learning and advanced analytics; computational power is no longer as expensive and constrained as it has been; the commercial sector is expanding; and new graduate students and faculty are bringing new ideas and enthusiasm. I hope this encyclopedia proves to be as useful and defining as it clearly has the potential to be, and I congratulate Dr. Sagar and his team once more on a magnificent achievement.

Preface

The past six decades have proved monumental in the discovery and accumulation of facts and detailed data on the solid earth, oceans, atmosphere, and space science. Now an established field, Mathematical Geosciences, covers the original approaches, while bringing new applications of well-established mathematical and statistical techniques to address the various challenges encountered. Pioneering academics and scientists who developed the inceptive fabric of mathematical geosciences, in chronological order, to name a few, including Andrey Kolmogorov (Probability Theory), Ronald Fisher (Mathematical Statistics), Danie Krige (Ore Reserve Valuation), William Christian Krumbein (Sedimentary Geology), John C Griffiths (Econometrics and Sedimentary Petrology), John Tukey (Exploratory Data Analysis), Georges Matheron (Geostatistics), Benoit Mandelbrot (Fractal Geometry), Frits Agterberg (Geomathematics), Geoffrey Watson (Directional Statistics), Daniel Merriam (Computational Geosciences), Jean Serra (Mathematical Morphology), Dietrich Stoyan (Stochastic Geometry), John Aitchison (Compositional Data Analysis), and William Newman (Complexity Science), are among many others who emerged as mathematical geoscientists during the last three decades. Some of the pioneering associations, besides the International Association for Mathematical Geosciences (IAMG), that promote mathematical geosciences include Society for Industrial and Applied Mathematics (SIAM), IEEE's Geoscience and Remote Sensing Society (GRSS), American Geophysical Union (AGU), European Geoscience Union (EGU), and the Indian Geophysical Union (IGU). With this backdrop, we have worked toward releasing the *Encyclopedia of Mathematical Geosciences* – as a sequel to *Dictionary of Mathematical Geosciences* and *Handbook of Mathematical Geosciences* published by Springer during the latter part of the last decade – receiving requisite attention from mathematicians and geoscientists alike, thus facilitating dialogue among the stakeholders to address outstanding issues in “Mathematics in Geosciences” in the years to come.

We bring scientists, engineers, and mathematicians together contributing chapters related to the geosciences, and we opine that this encyclopedia is essential for the next generation of geoscience researchers and educators. It provides more than 300 entries in a lucid manner concerned with relevant conventional and modern mathematical, statistical, and computational techniques for application in the geosciences and space science. Such a resource should be highly useful for the next generation of Mathematical Geoscientists. Chapters in this encyclopedia are of three categories. On much broader topics of relevance to the Mathematical Geosciences, experienced pioneers have contributed about 30 Category-A type chapters and about 265 Category-B type chapters on entries of relevance to the mathematical geosciences, while Category-C type chapters which are brief biographies of fifty pioneering mathematical geoscientists. Most existing papers and books published in the Mathematical Geosciences are introduced for mathematically inclined readers prepared to go through the texts from beginning to end. The main goal of this *Encyclopedia of Mathematical Geosciences* is to make important keyword-specific chapters accessible to readers interested in specific topics but lacking the time to peruse the more comprehensive publications in their areas of interest. This encyclopedia humbly provides comprehensive references to over 300 topics in the field of Mathematical Geosciences. Needless to say, keywords that are mathematically important but without established geoscientific relevance and keywords that are relevant to geosciences without direct

connection to mathematics were omitted. Each chapter was prepared in such a way that a layperson with high-school qualifications should be able to understand its content without too much difficulty. As much as possible, each chapter was prepared in a descriptive style with minimal mathematical jargon but directing the mathematically oriented readers to key references for further study. To our best, we have avoided redundancy in this two-volume encyclopedia, and we suggest that the reader refers to other encyclopedias in the Earth Science Series whenever needed.

A host of challenges of geoscientific relevance commands the attention of applied mathematicians. Addressing some of those challenges also offers opportunities as well as the need to advance the foundations and techniques of applied mathematics in order to meet the challenges. Further scope entails several other entries – from dynamical systems, ergodic theory, renormalization, and multiscaling – which possess high potential to address challenges encountered in the geosciences. Some challenges relevant to fluid and solid media – such as the Earth’s interior and exterior, analysis, simulation, and prediction of terrestrial processes, ranging from climate change to earthquakes, space sciences, etc. – command the involvement of dynamical systems and ergodic theory, renormalization, and topological data analysis.

While we like to receive feedback on what has been given emphasis within the gambit of “Mathematical Geosciences,” we also would like to explore what more needs to be done to broaden the portfolio of our scientific discipline. The encyclopedia will require revisions and updates at least once per decade. Its four editors reflect diverse disciplines and they have contributed significantly, from the EOMG’s inception stage to its release. The encyclopedia is available not only as a two-volume printed version but also as an online reference work at <http://springerlink.com> which will allow us to make regular updates as new entries and techniques emerge.

Acknowledgments

Half-a-Decade-long work in bringing the *Encyclopedia of Mathematical Geosciences* to its concluding stage was a herculean task. During the last 5 years (2018–2023), countless hours were spent on the listing of keyword-specific entries, inviting potential authors to contribute keyword-specific chapters, reviewing the submitted chapters, finalizing and forwarding them for subsequent work at the production department, and organizing the corrected galley proofs, followed by the preparation of preliminary content, and front and back matter. There was huge coordination involved throughout among authors, reviewers, sectional editors, editors, the staff of the Springer Nature Publishers, and the production department. We gratefully acknowledge the help and support of the authors ranging from multiple decades of experience to the new generation who have graciously contributed excellent chapters, investing their time, knowledge, and expertise. The basic idea of producing this encyclopedia came from Daya Sagar who subsequently by far has made the largest contribution to making this project a success. The other editors are grateful to him for his initiatives and guidance. This kind of project is successful mostly because of the support, cooperation, and guidance received from highly experienced senior colleagues; viz., Frits Agterberg, Ricardo Olea, Gabor Korvin, Eric Grunsky, John Schuenemeyer, and younger colleagues Jaya Sreevalsan-Nair and Lim Sin Liang, among others. We (Sagar, Cheng, and McKinley) owe a lot to Frits for his guidance and sharp memory, and we feel fortunate to have him and his 24×7 working style that has helped us past several hiccups during the past 5 years. Frits: We apologize for requiring your time very often even while you were hospitalized and ill for three months during the first quarter of 2021. The timely permissions granted/arranged for a few copyrighted media of information by Teja Rao, Laurent Mandelbrot, Karen Kafadar, Ramana Sonty, and Britt-Louise Kinnefors are gratefully acknowledged.

The considerable support received from Annett Buettner, Sylvia Blago, and Johanna Klute from Springer Nature Publishers is simply remarkable, and the efficiency, patience, relentless reminders, and strong-willed determination that they have shown throughout every phase of this monumental project are highly professional. The lion's share of the success should be theirs, besides the contributions of the authors.

About the Editors

B. S. Daya Sagar (born February 24, 1967) is a Full Professor of the Systems Science and Informatics Unit at the Indian Statistical Institute. Sagar received his MSc (1991) and PhD (1994) degrees in Geoengineering and Remote Sensing from the Andhra University, India. He worked at Andhra University (1992–1998), The National University of Singapore (1998–2001), and Multimedia University, Malaysia (2001–2007). Sagar has made significant contributions to the field of mathematical earth sciences, remote sensing, spatial data sciences, and mathematical morphology. He has published over 90 papers in journals and has authored or guest-edited 14 books or journal special issues. He authored *Mathematical Morphology in Geomorphology and GISci* (CRC Press, 2013, p. 546) and *Handbook of Mathematical Geosciences* (Springer, 2018, p. 942). He was elected a Fellow of Royal Geographical Society, an IEEE Senior Member, a Fellow of the Indian Geophysical Union, and a Fellow of the Indian Academy of Sciences. He was awarded the Dr. Balakrishna Memorial Award – 1995, the IGU-Krishnan Medal – 2002, the IAMG “Georges Matheron Award – 2011,” the IAMG Certificate of Appreciation – 2018 Award, and the IEEE-GRSS Distinguished Lecturership Award. He is a member of the AGU’s Honors and Recognition Committee (2022–23). He is (was) on the Editorial Boards of *Computers and Geosciences*, *Frontiers: Environmental Informatics*, and *Mathematical Geosciences*. He is the Co-Editor-in-Chief of the Springer’s *Encyclopedia of Mathematical Geosciences*.

Qiuming Cheng is currently a Professor at the School of Earth Science and Engineering, Sun Yat-Sen University, Zhuhai, and the Founding Director of the State Key Lab of Geological Processes and Mineral Resources, China University of Geosciences (Beijing, Wuhan). He received his PhD in Earth Science from the University of Ottawa under the supervision of Dr. Frits Agterberg in 1994. Qiuming was a faculty member at York University, Toronto, Canada (1995–2015). Qiuming has specialized in mathematical geoscience with a research focus on nonlinear mathematical modeling of earth processes and geoinformatics for mineral resources prediction. He has authored over 300 research articles. He received the IAMG’s Krumbein Medal – 2008 and the AAG’s Gold Medal – 2020. He is a member of the Chinese Academy of Sciences and a foreign member of the Academia Europaea. He was President of the IAMG (2012–2016) and President of the IUGS (2016–2020). He

has promoted broadening the scope of MG from more traditional statistical geology to interdisciplinary mathematical geosciences and the collaboration among geounions and other organizations on big data and geo-intelligence in solid earth science and geoscientific input to the Future Earth Program. He initialized and established the IUGS big science program on Deep-time Digital Earth (DDE).

Jennifer McKinley is Professor of Mathematical Geoscience, in Geography and Director of the Centre for GIS and Geomatics at Queen's University Belfast (QUB), UK. As a Chartered Geologist, her research has focused on the application of spatial analysis techniques, including geostatistics, spatial data analysis, compositional data analysis, and Geographical Information Science (GIS), to natural resource management, soil and water geochemistry, environmental and criminal forensics, human health and the environment, and nature-based solutions for urban environments. Jennifer's international leadership roles include Councilor of the International Union of Geosciences (IUGS 2020–2024), President of the Governing Council of the Deep-time Digital Earth Initiative (DDE 2020–2024), and Past President of the International Association of Mathematical Geoscientists (IAMG 2016–2020). Jennifer has served on learned committees including the Royal Irish Academy and Geological Society of London and sits on the Giant's Causeway UNESCO World Heritage Site Steering Group.

Frederik Pieter Agterberg (born November 15, 1936) is a Dutch-Canadian mathematical geoscientist. He obtained BSc (1957), MSc (1959), and PhD (1961) degrees at Utrecht University. After 1 year as WARF postdoctoral fellow at the University of Wisconsin, he joined the Canadian Geological Survey (GSC) as “petrological statistician.” In 1969, he formed the GSC Geomathematics Section, which he headed until his retirement in 1996 when he became a GSC Emeritus Scientist. “Frits” taught Statistics in Geology course at the University of Ottawa from 1968 to 1992 before becoming an Adjunct Professor in the Earth Science Department at the same university. From 1983 to 1989 he was also Adjunct Professor in Mathematics Department at Carleton University. He was instrumental in establishing the International Association for Mathematical Geosciences (IAMG) in 1968, received the IAMG's William Christian Krumbein Medal in 1978, and was IAMG President from 2004 to 2008. He was named IAMG Distinguished Lecturer in 2004 and IAMG Honorary Member in 2017. Frits was made Correspondent of the Royal Netherlands Academy of Arts and Sciences in 1981. He is the sole author of 4 books, editor or co-editor of 11 other books, and author or co-author of over 300 scientific publications. He was co-editor of the *Handbook of Mathematical Geosciences* published in 2018.

Accuracy and Precision

P. A. Dowd

School of Civil, Environmental and Mining Engineering,
The University of Adelaide, Adelaide, SA, Australia

Definitions

Accuracy is a measure of how close a measured value of a variable is to its true value. In the context of the mathematical geosciences, it could also be a measure of how close an estimated value of a variable is to the unknown true value at a given location when the estimate is obtained as some function of the measured data values. In the latter sense, the accuracy comprises two components: the accuracy of the measurements of the individual data values and the accuracy of the estimate based on those values.

Precision is a measure of the extent to which independent measurements of the same variable agree when using the same measuring device and procedure, i.e., the degree of reproducibility. Precision is also used to refer to the number of significant digits used in the specified measured value. For example, when comparing two measuring devices, if one can measure in smaller increments than the other, it has a higher precision of measurement. To distinguish this definition from the previous one, it will be referred to as the resolution of the measuring device.

As accuracy is independent of precision, a measurement may be precise but inaccurate or it may be accurate but not precise. It is difficult to achieve high accuracy without a good level of precision. A common way of illustrating the concepts of accuracy and precision is to use the game of darts where the objective is to throw multiple darts at a dart board with the objective of hitting the bull's eye at the center of the board. In terms of the accuracy and precision of the dart thrower, there are four general outcomes: (Fig. 1)

Both accuracy and precision are related to uncertainty. Uncertainty arises from the inability to measure a variable exactly and is quantified as the range of values of the variable within which the true value lies. The uncertainty may be due to the calibration of a measuring device or the manner in which a sample is collected and/or analyzed. Uncertainty also refers to the range of values of an estimated value of a variable when the estimate is obtained as some function of a set of measured data values.

The most common measure of accuracy is the relative error in a set of n measurements:

$$\frac{\sum_{i=1}^n |\text{measured value}_i - \text{true value}|}{\text{true value}}$$

The most common measure of precision is the coefficient of variation:

$$\frac{\sqrt{\frac{\sum_{i=1}^n (\text{measured value}_i - \text{mean measured value})^2}{n-1}}}{\text{mean measured value}}$$

The Mathematical Geosciences Context

Geoscience variables may be quantitative or qualitative. These variables may be measured directly by collecting physical samples and subjecting them to some process or they may be measured indirectly by using one or more of many sensing devices.

Quantitative variables are numerical and they measure specific quantities. They are generally measured on specific volumes and their values are averages over those volumes. For example, the gold content of a specific volume of rock is measured as the proportion of the volume of rock that is gold. As the variance of such variables is inversely proportional to the volume on which they are measured, values measured on different volumes should not be combined without accounting for the volume-variance effect.

Accuracy and Precision, Fig. 1

Qualitative (or categorical) variables may also be measured on specific volumes and they may be nominal (e.g., rock types or the presence or absence of a characteristic such as lithology) or ordinal (i.e., an ordered rank or sequence in which the distance between the elements is irrelevant). Examples of the latter include measures of mineral hardness or rock strength characteristics. Quantifying the uncertainty of qualitative variables is more problematic see, for example, Pulido et al. (2003) for examples of methods, and Lindsay et al. (2012) for quantifying geological uncertainty in three-dimensional modelling.

All geoscience variables are spatial in the sense that their values are a function of the location at which they are measured, and they generally have a level of spatial correlation that reflects the structure of the geological or geomorphological setting in which they occur.

The accuracy of a measurement of a variable can only be known if the true value of the variable is known. If the true value is not known, which is the case for many geoscience variables, then the accuracy of a measurement can only be estimated. Assuming that the measurement instrument is properly calibrated, and the approved measurement process is followed, a practical method of quantifying accuracy is by repeatedly measuring the same sample and expressing the accuracy as:

$$\frac{\sum_{i=1}^n |\text{measured}_i - \text{average}|}{\text{average}}$$

However, in the geosciences, often only some representative proportion of the entire sample is measured. In addition, the direct quantitative measurement of many types of samples requires destructive testing of a subsample of the total sample. A common example is measuring the mineral content of a cylindrical drill core sample. In common practice, the core is

split longitudinally, and one half is kept for reference. The other half-core is crushed to a given particle size and a subsample is taken, which is then crushed to a smaller particle size and again resampled. This procedure is repeated a number of times until a final subsample is obtained and chemically analyzed for mineral content. Each step of the procedure may introduce error and/or affect the representativity of the subsample and hence affect accuracy and precision. For a detailed account of the sampling of particulate materials, see Gy (1977) and Royle (2001). For a detailed approach to accuracy and precision in sampling particulate materials for analytical purposes, see Gy (1998). For quantifying uncertainty in analytical measurements see Ellison and Williams (2012).

Resolution of the Measuring Device: Significant Figures

It is useful to distinguish between exact numbers and measured numbers. An exact number is a number that is perfectly known. It could be a number obtained by counting items, such as the number of samples prepared for analysis. It could also be a defined number, such as $1 \text{ m} = 100 \text{ cm}$. Exact numbers have an infinite number of significant figures.

The interest here is in measured numbers, which are not exactly known because of the limitations of the measuring device and process, and in values that are calculated from measured numbers. An indication of the uncertainty of a measured value is the number of significant figures used to report it. Results of calculations should not be reported to a greater level of precision than the data. The rules for determining the number of significant figures are:

- Nonzero digits are always significant.
- Zeros between significant digits are significant. For example, 3045 has four significant digits.
- Zeros to the left of the first nonzero digit are not significant. For example, 0.00542 has three significant digits. This is clearer when using exponential notation: 5.42×10^{-3} .
- A final zero and all trailing zeros in the decimal portion of a number are significant. For example, the final two zeros in 0.0004700 in which there are four significant (4700) digits and 6.720×10^4 in which all zeros are significant.
- Trailing zeros are not significant in numbers without decimal points. For example, 250 has two significant figures and 5000 or 5×10^3 has only one significant digit.

Sensed Data

Some variables are not directly measured but are extracted from a signal generated by a sensing device. Such a device might be used locally (e.g., lowered into a drillhole to sense mineral grades at incremental depths) or used remotely (e.g., from a satellite or an aircraft to sense features of the surface of the Earth). Widely used subsurface sensing techniques include seismic tomography, magnetotellurics, and ground-penetrating radar. These signal data must be processed to extract the required quantitative or qualitative data. For quantitative variables, such as mineral grades, the depth that the signal penetrates the rock may differ depending on the local characteristics of the rock and thus each signal measurement at different locations may refer to different volumes. Such measurements cannot be combined without accounting for the volume-variance relationship.

Quantification of the accuracy and precision of sensed geoscience data has largely been limited to the surface of the Earth using techniques such as Landsat and LiDAR. These techniques can detect and measure surface features and generate two-dimensional and three-dimensional data with relatively high accuracy and precision. Congalton and Green (2020) is a good reference for quantifying the accuracy and precision of these techniques.

Quantifying the accuracy and precision of subsurface sensed data is more complex. In many cases, the detection of significant qualitative features is relatively accurate. However, it is much more difficult to quantify the accuracy and precision of quantitative measurements. The increasing use of sensed quantitative subsurface data requires some meaningful measure of accuracy and precision, especially when these data are integrated with directly measured data, which will have different levels of accuracy and precision.

An indication of the increasing use of subsurface sensed data for minerals, energy, and water resources, including the identification and reduction of all sources of uncertainty, can be found in the Deep Earth Imaging Project (CSIRO 2016).

Integrating Sensed and Directly Measured Data

Until recently, sensed data in the geosciences have largely been limited to qualitative geological and geomorphological characteristics and to quantitative variables on the surface, or near subsurface, of the earth particularly for applications such as hydrology (e.g., Reichle 2008). For subsurface applications, the exceptions have been quantitative variables, such as elastic moduli and rock-strength parameters, that can be derived from sensed variables such as shear velocity, compressive velocity, and bulk density; see Dowd (1997) for an example of deriving these variables from measured variables. Increasingly, direct quantitative subsurface sensing devices (e.g., measuring mineral grades while drilling) are being developed and implemented. In economic geology and mineral resource applications these sensed data are used together with directly measured values of the same characteristic or property (e.g., sensed mineral grade and directly measured grade) usually at different locations. This requires the two types of data to be integrated in a way that accommodates the different accuracies and uncertainties of the measured values and the different volumes of measurements. This is an area of ongoing research in many areas of the mathematical geosciences. See Careassi et al. (2018) for approaches in environmental modelling.

Using Integrated Data Types for Estimation

Quantitative data may be used to estimate the value of a variable at an unsampled location on the same volume as the data or, more often, on a significantly larger volume. Qualitative data may be used to estimate the presence or absence of a characteristic or feature at an unsampled location or to estimate the boundaries of features or in the various forms of geological domaining. These (statistical or geostatistical) estimates are, or should be, accompanied by a measure of the accuracy of the estimate. In this context, the accuracy refers to the uncertainty of the estimate. The estimate will also be reported with a level of precision.

For various reasons, more often than not, the measure of the uncertainty of the estimate does not include the uncertainty of the data used in the estimate. See de Marsily (1986) for kriging with uncertain data and an application in Cecinati et al. (2018). As the amount of sensed data increases, there is a corresponding need to account appropriately for the relative uncertainties of directly measured and sensed data especially in mineral resource applications and more generally in economic geology.

The data are also used to inform the model used for estimation; for example, the variogram used in geostatistical estimation (cf. Journel and Huijbregts 1978, 1984). The amount of data available, and their relative spatial locations,

will affect the quantification of spatial variability in the variogram model, which in turn will affect the accuracy of estimates. The various forms of kriging yield estimation variances that quantify the accuracy of the estimate, but the quantification does not generally include the uncertainty of the parameters in the variogram model. In addition, sparse data at significant distances from the location at which the estimate is made will overestimate low values and underestimate high values (Goovaerts 1997), thus affecting the accuracy and precision of the estimate. There is a need, especially in economic geology and mineral resource estimation, for the adequate incorporation of these sources of uncertainty in the estimates.

Summary

This entry summarizes the concepts of accuracy and precision in the context of the mathematical geosciences. Both concepts relate to direct, and sensed, in situ measurements of variables, to the integration of these two types of measurement, to the quantification of the spatial variability of these two types of measurement, and to the use of the measurements to estimate values of variables at unsampled locations. It also identifies areas that require further research to enable a greater understanding of accuracy and precision and to include additional sources of uncertainty that affect accuracy and precision.

Logistic normal; Logratio normal; Normal on the simplex

Definition

The *additive logistic normal* model is a family of distributions of compositional data defined on the simplex using the logratio approach (Aitchison 1986; Pawlowsky-Glahn et al. 2015) and the multivariate normal distribution for real random vectors. It is the most used distribution on the simplex introduced by Aitchison (1982) as an alternative to the well-known Dirichlet model. For the construction of the distribution, standard strategy of the logratio methodology using the principle of working on coordinates is applied; specifically, the multivariate normal distribution in the real space is used to model the additive logratio representation of the random composition.

Originally, the model was defined using the additive logratio (alr) representation, and hence the name additive

logistic normal was assigned. However, other orthonormal logratio representations, originally known as isometric logratio (ilr) representation (Egozcue et al. 2003), can be used too. For this reason, the term isometric logistic normal or, more general, the term logistic normal is adopted for this model as well. Later, motivated by the principle of working on coordinates the term normal distribution on the simplex comes to emphasize the idea of staying on the simplex (Mateu-Figueras et al. 2013). Nowadays, the term logratio normal is also preferred by some authors (Comas-Cufi et al. 2016) to highlight the use of logratio coordinates instead of logistic transformation.

Sample Space of Compositional Data and Its Geometry

The content of this section is largely covered in the chapter ▶ “Additive Logistic Skew-Normal Distribution,” and more extended in the chapter ▶ “Compositional Data”. For readers’ convenience, we introduce here only notation and some essential concepts useful in the following.

The simplex is the sample space of random compositions with D parts. It is denoted as

$$\mathcal{S}^D = \left\{ \mathbf{x} = (x_1, \dots, x_D), x_i > 0, i = 1, 2, \dots, D, \sum_{i=1}^D x_i = \kappa \right\},$$

where κ is a constant, usually taken to be 1 or 100.

The simplex $\mathcal{S}^D$ has a $(D - 1)$ -dimensional real Euclidean vector space structure with the following operations (Pawlowsky-Glahn et al. 2015):

- Perturbation: $\mathbf{x} \oplus \mathbf{y} = \mathcal{C}(x_1 y_1, \dots, x_D y_D)$,
- Powering: $\alpha \odot \mathbf{x} = \mathcal{C}(x_1^\alpha, \dots, x_D^\alpha)$,
- Inner product: $\langle \mathbf{x}, \mathbf{y} \rangle_a = \sum_{i=1}^D \ln \frac{x_i}{g_m(\mathbf{x})} \ln \frac{y_i}{g_m(\mathbf{y})}$,

for $\mathbf{x}, \mathbf{y} \in \mathcal{S}^D$, a scalar $\alpha \in \mathbb{R}$, $g_m(\mathbf{x})$ the geometric mean of the parts of $\mathbf{x}$, and $\mathcal{C}$ the *closure* operator which normalizes any vector to the constant sum κ .

This algebraic-geometric structure of the sample space assures existence of a basis and the corresponding coordinate representation of compositions. These coordinates are real vectors that obey the standard Euclidean geometry. Consequently, once a basis has been chosen, all standard geometric operations, or statistical methods, can be applied to compositional data in coordinates and transferred to the simplex by preserving their properties. This is known as the *principle of working on coordinates* (see the ▶ “Compositional Data” entry). Some frequently used coordinate representations are:

- $\text{alr}(\mathbf{x}) = \left(\ln \frac{x_1}{x_D}, \dots, \ln \frac{x_{D-1}}{x_D} \right) \in \mathbb{R}^{D-1}$,

- $\text{clr}(\mathbf{x}) = \left(\ln \frac{x_1}{g_m(\mathbf{x})}, \dots, \ln \frac{x_D}{g_m(\mathbf{x})} \right) \in \mathbb{R}^D$, where $\sum_{i=1}^D \ln \frac{x_i}{g_m(\mathbf{x})} = 0$,
- $h(\mathbf{x}) = (\langle \mathbf{x}, \mathbf{e}_1 \rangle_a, \dots, \langle \mathbf{x}, \mathbf{e}_{D-1} \rangle_a) \in \mathbb{R}^{D-1}$, where $\{\mathbf{e}_1, \dots, \mathbf{e}_{D-1}\}$ is an orthonormal basis on $\mathcal{S}^D$.

Note that vectors $\text{alr}(\mathbf{x})$ and $\text{clr}(\mathbf{x})$, where the latter stands for centered logratio (clr) coefficients, are non-orthogonal logratio representations. In particular the clr representation has one extra dimension, which makes it a constrained vector. Vector $h(\mathbf{x})$ is an orthonormal logratio representation. It contains the coordinates of $\mathbf{x}$ with respect to the orthonormal basis $\{\mathbf{e}_1, \dots, \mathbf{e}_{D-1}\}$. Egozcue et al. (2003) introduced it using a particular orthonormal basis naming it *isometric logratio* (ilr($\mathbf{x}$)) representation. Quite recently, Martín-Fernández (2019) renamed it as *orthogonal logratio* (olr($\mathbf{x}$)) representation to emphasize this intrinsic property. There are some popular possibilities how to build such an orthonormal basis (Egozcue and Pawlowsky-Glahn 2005; Filzmoser et al. 2018). In order to avoid confusion, here we will denote a generic orthonormal representation as $h(\mathbf{x})$. Also, given a real vector of olr coordinates $\mathbf{y}$ we will denote the corresponding composition as $h^{-1}(\mathbf{y})$. The different logratio coordinate representations can be linked through the change of basis matrix.

We briefly review the concept of *subcomposition*, used in the remainder of the chapter. Given a random composition $\mathbf{X} \in \mathcal{S}^D$, a C -part subcomposition is a subvector in $\mathcal{S}^C$ formed only by C parts ($C < D$). A subcomposition can be obtained as $\mathcal{C}(\mathbf{S}\mathbf{X})$ where $\mathbf{S}$ is a (C, D) -matrix with C elements equal 1 (one in each row and at most one in each column) and the remaining elements equal 0.

Furthermore, to define probability laws it is important to establish a measure with respect to which our density function is expressed. Traditionally, a Lebesgue measure λ has been used in the simplex, but the *Aitchison measure* λ_a is preferred in the context of the Aitchison geometry (Mateu-Figueras and Pawlowsky-Glahn 2008). It could be proved that λ_a is absolutely continuous with respect to λ . The relationship between them is described by the Jacobian

$$\frac{d\lambda_a}{d\lambda} = \frac{1}{\sqrt{D} \prod_{i=1}^D x_i}, \quad (1)$$

and allows to express density functions on $\mathcal{S}^D$ with respect to either λ or λ_a .

The Logistic Normal Model

Definition

The additive logistic normal (aln) model is defined by Aitchison (1982) using the alr coordinates. Indeed, a D -part random composition $\mathbf{X}$ is said to have an aln distribution when its additive logratio representation, $\text{alr}(\mathbf{X})$, has a $(D - 1)$ -dimensional normal distribution in the space of

coordinates. The corresponding density function on $\mathcal{S}^D$ with respect to the λ measure is

$$f(\mathbf{x}) = \frac{(2\pi)^{-(D-1)/2} |\Sigma|^{-1/2}}{\prod_{i=1}^D x_i} \exp\left(-\frac{1}{2} (\text{alr}(\mathbf{x}) - \boldsymbol{\mu})' \Sigma^{-1} (\text{alr}(\mathbf{x}) - \boldsymbol{\mu})\right). \quad (2)$$

This distribution will be denoted as $\mathbf{X} \sim \mathcal{N}_{\mathcal{S}}^D(\boldsymbol{\mu}, \Sigma)$ (Mateu-Figueras et al. 2013). Note that the total number of parameters of an aln distribution is $(D-1)(D+2)/2$.

We could express density (2) in terms of any orthonormal logratio representation $h(\mathbf{X})$. We have to use only the matrix relationship between the two logratio representations $h(\mathbf{X}) = \mathbf{A} \text{alr}(\mathbf{X})$ (see the ► “Additive Logistic Skew-Normal Distribution” entry for the matrix $\mathbf{A}$) and the linear transformation property of the normal distribution. The resulting density is defined on the simplex and also expressed with respect to the Lebesgue measure λ :

$$f(\mathbf{x}) = \frac{(2\pi)^{-(D-1)/2} |\mathbf{Y}|^{-1/2}}{\sqrt{D} \prod_{i=1}^D x_i} \exp\left(-\frac{1}{2} (h(\mathbf{x}) - \boldsymbol{\xi})' \mathbf{Y}^{-1} (h(\mathbf{x}) - \boldsymbol{\xi})\right), \quad (3)$$

where

$$\boldsymbol{\xi} = \mathbf{A}\boldsymbol{\mu}, \quad \mathbf{Y} = \mathbf{A}\Sigma\mathbf{A}'. \quad (4)$$

A similar strategy could be applied to obtain the density in terms of the clr representation, but it has a limited use in practice as a degenerate density is obtained due to the zero-sum constraint of the vector $\text{clr}(\mathbf{X})$.

Both densities (2) and (3) define exactly the same probability law on $\mathcal{S}^D$ and are defined with respect to the Lebesgue

measure λ . Using the relationship (1), it is easy to express it with respect to the Aitchison measure λ_a as

$$f_a(\mathbf{x}) = (2\pi)^{-(D-1)/2} |\mathbf{Y}|^{-1/2} \exp\left(-\frac{1}{2} (h(\mathbf{x}) - \boldsymbol{\xi})' \mathbf{Y}^{-1} (h(\mathbf{x}) - \boldsymbol{\xi})\right); \quad (5)$$

here the subindex a is only used to remind that the density is expressed with respect to λ_a . Mateu-Figueras et al. (2013) define the logistic normal model using density (5) and call it the *normal distribution on the simplex*. Even though this change of measure gives the same law of probability, it produces changes in some characteristic values of the distribution. An interested reader can find a detailed explanation in Mateu-Figueras et al. (2013). We advise that if we want to study properties of the distribution directly on the simplex, it is better to use the density with respect to the Aitchison measure as it is compatible with the simplex space structure. Moreover, the Aitchison measure enables further generalization of the logistic normal distribution, if parts of the random composition are weighted, for example, according to measurement precision (Egozcue and Pawlowsky-Glahn 2016; Hron et al. 2022). However, for computation of probability of an event we have to use the density with respect to the Lebesgue measure in order to compute the integrals.

In Fig. 1 we represent the isodensity curves of two logistic normal densities on (a) $\mathcal{S}^3$ with respect to λ_a and on (b) $\mathbb{R}^2$ using the orthonormal logratio representation with respect to the particular orthonormal basis defined in Egozcue et al. (2003). Note that using the coordinate representation, the typical circumferences and ellipses from the multivariate normal in real space are obtained as isodensity curves. The isodensity curves on the simplex are the corresponding logratio circumferences and logratio ellipses.

Additive Logistic Normal

Distribution, Fig. 1 Isodensity curves of two logistic normal models in (a) on $\mathcal{S}^3$ and (b) on $\mathbb{R}^2$ using an orthonormal logratio representation. The solid line stands for $\boldsymbol{\xi} = (1, 0)$, $\mathbf{Y} = \mathbf{I}$ and the dash-dotted line for

$$\boldsymbol{\xi} = (-1, 1), \mathbf{Y} = \begin{pmatrix} 0.2 & 0.8 \\ 0.8 & 6 \end{pmatrix}$$

Key Properties

Real random vectors obtained as linear transformation of a multivariate normal distribution on real space are still multivariate normal distributed. This is the well-known linear transformation property of the multivariate normal. Applying this property to the logratio vectors, we can easily prove the closure under perturbation, power transformation, and subcomposition of the logistic normal family of distributions. We list here the main properties using the density in terms of the logratio representation $h(\mathbf{x})$ with respect to a generic orthonormal basis, but the density in terms of the $\text{alr}(\mathbf{x})$ could also be used. An interested reader can find a detailed proof of each property in Mateu-Figueras et al. (2013).

Property 1 (Closure under $\oplus$ and $\odot$) Let $\mathbf{X} \sim \mathcal{N}_{\mathcal{S}}^D(\xi, \mathbf{Y})$ be a random composition, $\mathbf{a} \in \mathcal{S}^D$, and $b \in \mathbb{R}$. Then, the D -part random composition $\mathbf{X}^* = \mathbf{a} \oplus (b \odot \mathbf{X}) \sim \mathcal{N}_{\mathcal{S}}^D(h(\mathbf{a}) + b\xi, b^2\mathbf{Y})$.

From this property, and using the density function with respect to the Aitchison measure λ_a , we obtain the invariance under perturbation operation, that is, $f_a(\mathbf{a} \oplus \mathbf{x}) = f_a(\mathbf{x})$. This has important consequences, because when working with compositional data, it is usual to center the input data set which could be expressed as perturbation by a compositional vector (center of the distribution). However, this property would not be obtained using the density with respect to the measure λ . Accordingly, although both densities define the same probability law, this is one of differences between them.

Property 2 (Closure under subcomposition) Let $\mathbf{X} \sim \mathcal{N}_{\mathcal{S}}^D(\xi, \mathbf{Y})$ and $\mathbf{X}_S = \mathcal{C}(\mathbf{S}\mathbf{X})$ be a C -part random subcomposition. Then $\mathbf{X}_S \sim \mathcal{N}_{\mathcal{S}}^D(\xi_S, \mathbf{Y}_S)$ with

$$\xi_S = \mathbf{U}^* \mathbf{S} \mathbf{U} \xi, \quad \mathbf{Y}_S = (\mathbf{U}^* \mathbf{S} \mathbf{U}) \mathbf{Y} (\mathbf{U}^* \mathbf{S} \mathbf{U})',$$

where the columns of matrices $\mathbf{U}$ and $\mathbf{U}^*$ contain the clr representation of the corresponding orthonormal basis in $\mathcal{S}^D$ and $\mathcal{S}^C$.

The center of a random composition $\mathbf{X}$ plays the role of the expected value for a real random vector (Pawlowsky-Glahn et al. 2015). Mateu-Figueras et al. (2013) show that this center can be expressed as the expected value using the density function with respect to λ_a ; for this reason it is denoted as $E_a(\mathbf{X})$.

Property 3 (Location) Let $\mathbf{X} \sim \mathcal{N}_{\mathcal{S}}^D(\xi, \mathbf{Y})$, then mode and expected value with respect to the measure λ_a coincide and are $\text{mode}_a(\mathbf{X}) = E_a(\mathbf{X}) = h^{-1}(\xi)$ independently of the chosen orthonormal coordinates $h(\mathbf{x})$.

The expected value with respect to the Lebesgue measure corresponds to the standard expected value for real random vectors. Although it exists, there is no closed form for this

value because the corresponding integral is not reducible to any simple form, and numerical integration should be used. Nevertheless, for random compositions, the use of $E_a(\mathbf{X})$ is recommended with the same arguments as, when working with a compositional data set, the center, that is the sample geometric mean, is used instead of the arithmetic mean.

Variability of random compositions can be measured with the metric variance, also called the total variance (Aitchison 1986).

Property 4 (Metric variance) Let $\mathbf{X} \sim \mathcal{N}_{\mathcal{S}}^D(\xi, \mathbf{Y})$, then $\text{Mvar}(\mathbf{X}) = \text{trace}(\mathbf{Y})$.

Given a compositional data set, the parameters of the logistic normal model, that is, the vector of expected values ξ and the covariance matrix $\mathbf{Y}$, may be estimated using the maximum likelihood method based on the logratio representation of the data set. If we change the logratio representation, the estimates will be related through the corresponding transformation matrix $\mathbf{A}$ as done in (4), the only deviations will be due to the numerical nature of the procedure. Thus, the estimates are invariant under the choice of the logratio representation.

Finally, given a compositional data set, we can validate the assumption of the logistic normality via testing for multivariate normality of the olr coordinate representation using a proper goodness-of-fit test. In this case, any univariate normality tests applied to each marginal are not invariant under the choice of the logratio representation, but the χ^2 goodness-of-fit test applied to the Mahalanobis distances or the multivariate Shapiro-Wilk test of normality is invariant.

Applications to Geosciences

In this section, by means of some compositional data analysis, we briefly show the central role of the logistic normal distribution in geosciences.

As the normal distribution in real space, the logistic normal distribution is used in many statistical compositional applications and represents an essential distribution for statistical inference on the simplex, such as regression analysis, hypotheses testing, and construction of confidence intervals.

We consider, as a first example, the GEMAS data set (Reimann et al. 2014a, b), a geochemical data set on agricultural and grazing land soil, collected as GEMAS data in the R-package robCompositions (Templ et al. 2011), to show the fit of the logratio normal distribution. Here the complementary particle size distributions are considered, that is, the three-part compositions $\mathbf{x} = (\text{sand}, \text{silt}, \text{clay})$. For this example only samples from Italy are used and filtered from outliers (Filzmoser and Hron 2008), resulting in $n = 109$ soil samples. Using the orthonormal logratio representation called pivot coordinates

$h(\mathbf{x}) = \left(\sqrt{2/3} \ln(\text{sand}/(\text{silt} \cdot \text{clay})^2), \sqrt{1/2} \ln(\text{silt}/\text{clay}) \right)$ (Filzmoser et al. 2018), the following parameter estimates are obtained: $\hat{\xi} = (0.245, 0.346)$ and $\hat{\Sigma} = \begin{pmatrix} 0.285 & 0.031 \\ 0.031 & 0.084 \end{pmatrix}$. Goodness-of-

fit tests applied to each marginal show no significant departures from normality (p -values > 0.1 for the Anderson-Darling and Shapiro-Wilk test). The Anderson-Darling test applied to the Mahalanobis distances to check the χ^2_2 assumption shows no significant departure (p -value > 0.1). The fitted isodensity curves on $\mathcal{S}^3$ are displayed in Fig. 2.

For the multivariate analysis of variance (MANOVA) to test whether significant differences exist in the three-part compositions of particle size distributions among soil groups, the multivariate logistic normality is one of the fundamental assumptions. In other words, we assume that the dependent variables, that is, the (sand, silt, clay) compositions follow the multivariate logistic normality within groups defined by the soil classes. The Shapiro-Wilk test for multivariate normality applied to the two pivot coordinates shows no significant strong departures from the null hypothesis (p -values $= 0.1$).

Figure 3 reports Normal Q-Q plots of the residuals of the MANOVA for the two pivot coordinates, which confirm that a

Additive Logistic Normal Distribution, Fig. 2 Fitted isodensity curves for the logistic normal model to the composition (sand, silt, clay) of the GEMAS data set. Samples from Italy were taken and filtered from outliers ($n = 109$)

Additive Logistic Normal Distribution, Fig. 3 Q-Q plots of the residuals of the MANOVA (GEMAS data set)

normal distribution is reasonable in both cases. Finally, the MANOVA test suggests significant differences between the soil groups (p -value < 0.001 for the Pillai test). Note that we would obtain the same inference in multivariate linear regression, using the soil classes as categorical covariate.

Similar to the MANOVA, also Linear Discriminant Analysis (LDA) for compositions, principal component analysis, or canonical correlation are other techniques which use the assumption of logistic normality to represent group distributions.

For demonstration purposes, we use a second example related to whole-rock composition of lavas from the Atacazo and Ninahuilca volcanoes, Ecuador (Hidalgo et al. 2008). In particular, we look at the major elements (sub)composition with five parts: Fe_2O_3 , MgO , K_2O , La , and Yb . The logistic normality assumption is confirmed by the univariate p -values of the Shapiro-Wilk tests applied to each pivot coordinate listed in Table 1; all reported p -values are greater than 0.05 within each level of the grouping variable, related to different volcanoes. Moreover, the last row of Table 1 reports results of the Shapiro-Wilk test for multivariate normality within the two groups, which again are compatible with the assumption.

The purpose of LDA in this example is to find the linear combinations of the original variables, namely the four pivot coordinates, that gives the best possible separation between groups in the data set. The LDA results offer a satisfactory separation of the two groups; in fact the model accuracy is equal to 0.945. The discriminant scores themselves are approximately normally distributed within groups as we can see from Fig. 4.

Summary

In this chapter the logistic normal model, a follower of the additive logistic normal distribution compatible with the algebraic-geometric structure of the simplex, was presented as a general tool for distributional modeling of compositional data in geosciences. It is flexible enough to model data

Additive Logistic Normal Distribution, Table 1 Results of univariate, and multivariate (last row), Shapiro-Wilk normality test (test statistics *W* and *p*-values) within groups

Pivot coordinates	Group Atacazo		Group Ninahuilca	
	<i>W</i>	<i>p</i> -value	<i>W</i>	<i>p</i> -value

Additive Logistic Normal Distribution, Fig. 4 Histograms of discriminant scores with superimposed normal curve, whose parameters are estimated from the respective scores means and standard deviations

coming from a wide-ranging applications, providing a sensible alternative to the well-known Dirichlet distribution which is not fully compatible with the logratio approach (Pawlowsky-Glahn et al. 2015). For all these reasons, logistic normal is considered the main distribution for compositional data.

Definition

The *additive logistic skew-normal* model is a family of distributions of compositional data defined on the simplex using the logratio approach (Aitchison 1986; Pawłowsky-Glahn et al. 2015) and the multivariate skew-normal distribution for real random vectors (Azzalini and Capitanio 1999). For the construction of the distribution standard strategy of the logratio methodology using the principle of working on coordinates is applied, specifically, the multivariate skew-normal distribution in the real space is used to model the additive logratio representation of the random composition. This model represents a generalization of the additive logistic normal model because it is contained as a particular case. This distribution allows us to model compositional data sets when their logratio representation displays low or moderate level of skewness and as such, it is appropriate for modeling of compositional data in geosciences.

Originally, the model was defined using the additive logratio representation, hence the name additive logistic skew-normal was assigned. However, other logratio representations such as the orthonormal logratio (olr) representation (Martín-Fernández 2019), originally known as isometric logratio (ilr) representation (Egozcue et al. 2003), can also be used. For this reason, the term logistic skew-normal or logratio skew-normal can be used to refer this distribution model.

Sample Space of Compositional Data and Its Geometry

The sample space of random compositions, where the logistic skew-normal model is defined, is called the simplex and is denoted as

$$\mathcal{S}^D = \left\{ \mathbf{x} = (x_1, \dots, x_D), x_i > 0, \sum_{i=1}^D x_i = \kappa \right\},$$

where κ is a constant, usually taken to be one (proportional representation of compositional data) or one hundred (representation in percentages). Below the algebraic geometric structure of the simplex, contained also in the entry ▶ “Compositional Data”, is briefly recalled for the purpose of this chapter.

The simplex $\mathcal{S}^D$ has a $(D - 1)$ -dimensional real Euclidean vector space structure with the following operations (Pawłowsky-Glahn et al. 2015):

- Perturbation: $\mathbf{x} \oplus \mathbf{y} = C(x_1 y_1, \dots, x_D y_D)$,
- Powering: $\alpha \odot \mathbf{x} = C(x_1^\alpha, \dots, x_D^\alpha)$,

for $\mathbf{x}, \mathbf{y} \in \mathcal{S}^D$ and a scalar $\alpha \in \mathbb{R}$. The operator C is the *closure* and normalizes the compositional vector in the argument by dividing each component by the sum of all components and multiplying them by the constant κ . Also, an inner product can be defined, that induces a norm and a distance (see the ▶ “Compositional Data” entry for details).

This algebraic-geometric structure of the sample space assures existence of a basis and the corresponding coordinate representation of compositions. These coordinates are real vectors that obey the standard Euclidean geometry, with the sum of two vectors and the multiplication of a vector by a scalar instead of perturbation and powering. Consequently, once a basis has been chosen, all standard geometric operations or statistical methods can be applied to coordinates and transferred to the simplex by preserving their properties. This is known as the *Principle of working on coordinates* (see the ▶ “Compositional Data” entry).

Some frequently used coordinate representations defined by Aitchison (1986) involve logratios:

$$\text{alr}(\mathbf{x}) = \left(\ln \frac{x_1}{x_D}, \dots, \ln \frac{x_{D-1}}{x_D} \right)$$

$$\text{clr}(\mathbf{x}) = \left(\ln \frac{x_1}{g_m(\mathbf{x})}, \dots, \ln \frac{x_D}{g_m(\mathbf{x})} \right)$$

The *additive logratio* (alr) representation is a $(D - 1)$ -dimensional vector which corresponds to coordinates with respect to an oblique basis. Consequently, the geometric operations are preserved as $\text{alr}(\mathbf{x} \oplus \mathbf{y}) = \text{alr}(\mathbf{x}) + \text{alr}(\mathbf{y})$ and $\text{alr}(\alpha \odot \mathbf{x}) = \alpha \cdot \text{alr}(\mathbf{x})$, but distances and orthogonal projections computed using the alr coordinates will not be the same as computed with the original compositions and using the Aitchison distance or inner product. This is the main drawback of the additive logratio coordinates. The *centered logratio* (clr) representation is a D -dimensional vector obtained as coefficients with respect to a generating system,

not coordinates of a basis. We have one extra dimension and for this reason the clr vector is constrained: the sum of its components equals to zero. Although this representation is widely used in the literature because geometric operations, distances and inner product are preserved, its use to define families of distributions is very limited because degenerate densities are obtained.

We can also consider coordinates with respect to an orthonormal basis, initially called as *isometric logratio* (ilr) representation, but recently renamed to *orthogonal logratio* (olr) representation which better reflects its intrinsic properties. Egozcue et al. (2003) proposed a particular orthonormal basis for construction of these coordinates, but there are also other popular possibilities how to build such a basis. One of them, explained in the ► “Compositional Data” entry, is using a sequential binary partition of a generic composition and called balances (Egozcue and Pawłowsky-Glahn 2005). Some other olr coordinate systems, called pivot coordinates, highlight the role of single compositional parts and were proposed in Filzmoser et al. (2018). In order to avoid confusion, here we will denote a generic orthonormal representation as $h(\mathbf{x})$. Also, given a real vector of olr coordinates $\mathbf{y}$ we will denote the corresponding composition as $h^{-1}(\mathbf{y})$.

Different logratio coordinate representations can be linked through a matrix which stands for the change of the basis. For example, we can construct a $(D-1) \times (D-1)$ matrix $\mathbf{A}$ which relates the alr representation with a particular orthonormal representation $h(\mathbf{x})$ as

$$h(\mathbf{x}) = \mathbf{A} \text{alr}(\mathbf{x}) \text{ or } \text{alr}(\mathbf{x}) = \mathbf{A}^{-1}h(\mathbf{x}) \quad (1)$$

where $\mathbf{A} = \mathbf{U}'\mathbf{F}^*$, $\mathbf{U}$ is a $(D, D-1)$ -matrix which contains in columns the clr representation of the orthonormal basis and $\mathbf{F}^*$ is the $(D, D-1)$ -matrix

$$\mathbf{F}^* = \frac{1}{D} \begin{pmatrix} D-1 & -1 & \dots & -1 \\ -1 & D-1 & \dots & -1 \\ \vdots & \vdots & \ddots & \vdots \\ -1 & -1 & \dots & D-1 \\ -1 & -1 & \dots & -1 \end{pmatrix}$$

Given a D -part random composition $\mathbf{X}$, we can be interested in the composition formed only by C -parts ($C < D$). This can be regarded as a projection on a simplex with fewer parts and, accordingly, a random *subcomposition* is obtained. Formally, the formation of a subcomposition can be achieved as $C(\mathbf{S}\mathbf{X})$ where $\mathbf{S}$ is a (C, D) -matrix with C elements equal 1 (one in each row and at most one in each column) and the remaining elements equal 0.

To define probability laws it is important to establish a measure with respect to which our density function is expressed. Traditionally, a Lebesgue measure λ has been

used in the simplex but the alternative measure called *Aitchison measure* and denoted as λ_a is preferred in context of the Aitchison geometry (Mateu-Figueras and Pawłowsky-Glahn 2008). This measure is defined using the Lebesgue measure in the space of olr coordinates and it is compatible with the vector space structure defined above. It could be proved that the Aitchison measure λ_a is absolutely continuous with respect to the Lebesgue measure λ . The relationship between them is

$$\frac{d\lambda_a}{d\lambda} = \frac{1}{\sqrt{D}\prod_{i=1}^D x_i}. \quad (2)$$

This relationship allows to express density functions on $\mathcal{S}^D$ with respect to λ or λ_a . Specifically, the chain rule for measures relates two probability densities, $dP/d\lambda_a$ and $dP/d\lambda$, as $dP/d\lambda = (dP/d\lambda_a)(d\lambda_a/d\lambda)$.

The Multivariate Skew-Normal Model

According to the definition given by Azzalini and Capitanio (1999), a $(D-1)$ -variate random vector $\mathbf{Y}$ follows a multivariate *skew-normal* (sn) distribution on $\mathbb{R}^{D-1}$ with parameters $\boldsymbol{\mu}$, Σ , and $\boldsymbol{\alpha}$, if its density function is given by

$$f(\mathbf{y}) = 2(2\pi)^{-(D-1)/2} |\Sigma|^{-1/2} \exp\left(-\frac{1}{2}(\mathbf{y} - \boldsymbol{\mu})' \Sigma^{-1}(\mathbf{y} - \boldsymbol{\mu})\right) \Phi(\boldsymbol{\alpha}' \boldsymbol{\omega}^{-1}(\mathbf{y} - \boldsymbol{\mu})), \quad (3)$$

where Φ is the standard normal distribution function and $\boldsymbol{\omega}$ is the square root of the diagonal matrix formed from Σ . The $(D-1)$ -variate vector $\boldsymbol{\alpha}$ regulates the shape of the density and indicates the direction of maximum skewness. The sn family is only able to model moderate levels of skewness as the skewness coefficient of each univariate sn marginal takes values in the interval $(-0.995, 0.995)$. When $\boldsymbol{\alpha} = 0$, the multivariate normal density with parameters $\boldsymbol{\mu}$ and Σ is obtained. In the following the notation $\mathbf{Y} \sim \mathcal{SN}^{D-1}(\boldsymbol{\mu}, \Sigma, \boldsymbol{\alpha})$ is used.

The moment generating function provided in Azzalini and Capitanio (1999) is

$$M\mathbf{Y}(t) = 2 \exp(t' \boldsymbol{\mu} + (1/2)t' \Sigma t) \Phi(\boldsymbol{\delta}' \boldsymbol{\omega} t), \quad (4)$$

where

$$\boldsymbol{\delta} = \frac{\boldsymbol{\omega}^{-1} \Sigma \boldsymbol{\omega}^{-1} \boldsymbol{\alpha}}{\sqrt{1 + \boldsymbol{\alpha}' \boldsymbol{\omega}^{-1} \Sigma \boldsymbol{\omega}^{-1} \boldsymbol{\alpha}}} \quad (5)$$

The expected value and the covariance matrix derived from (4) are

$$E(\mathbf{Y}) = \boldsymbol{\mu} + \boldsymbol{\omega} \sqrt{2/\pi} \boldsymbol{\delta}, \quad \text{Var}(\mathbf{Y}) = \boldsymbol{\Sigma} - (2/\pi) \boldsymbol{\omega} \boldsymbol{\delta} \boldsymbol{\delta}' \boldsymbol{\omega}$$

The appealing properties of this distribution are listed by Azzalini and Capitanio (1999). Most of them are analogues of the multivariate normal properties, in particular, random vectors obtained as linear transformation of the form $\mathbf{Y}^* = \mathbf{A}\mathbf{Y}$ for any real matrix $\mathbf{A}$, are still multivariate sn distributed. Another interesting property in connection with the multivariate normal random compositions is that the random variable

$$Z = (\mathbf{Y} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{Y} - \boldsymbol{\mu}), \quad (6)$$

follows a χ^2 distribution with $D - 1$ degrees of freedom.

Given a random sample, the maximum likelihood (ML) method is proposed to estimate the parameters but numerical procedures have to be used. The method of moments is proposed to obtain starting values for the iterative procedure. The R-package “sn” is available and contains a suite of functions for handling univariate and multivariate sn distributions (Azzalini 2020).

The Logistic Skew-Normal Model

Definition

By analogy with the additive logistic normal (aln) model defined by Aitchison (1986) using the alr coordinates, Mateu-Figueras et al. (2005) use the same strategy to define the additive logistic skew-normal (alsn) model. Indeed, a D -part random composition $\mathbf{X}$ is said to have an alsn distribution when its additive logratio representation, $\text{alr}(\mathbf{X})$, has a $(D - 1)$ -dimensional sn distribution in the space of coordinates. The corresponding density function on S^D with respect to the Lebesgue measure λ is

$$f(\mathbf{x}) = \frac{2(2\pi)^{-(D-1)/2} |\boldsymbol{\Sigma}|^{-1/2}}{\prod_{i=1}^D x_i} \exp\left(-\frac{1}{2} (\text{alr}(\mathbf{x}) - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\text{alr}(\mathbf{x}) - \boldsymbol{\mu})\right) \Phi(\boldsymbol{\alpha}' \boldsymbol{\omega}^{-1} (\text{alr}(\mathbf{x}) - \boldsymbol{\mu})). \quad (7)$$

This distribution will be denoted as $\mathbf{X} \sim \mathcal{SN}_S^D(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \boldsymbol{\alpha})$. A particular member of this class of distributions is determined by $(D - 1)(D + 4)/2$ parameters, $D - 1$ more than the aln class due to the $\boldsymbol{\alpha}$ vector. The aln model is obtained as a particular case when $\boldsymbol{\alpha} = \mathbf{0}$. For this reason, we can say that the alsn model is a generalization of the aln model.

We could express the density function in terms of any orthonormal logratio representation. We have only to use the matrix relationship between $h(\mathbf{X})$ and $\text{alr}(\mathbf{X})$ coordinates (1) and the linear transformation property of the sn

distribution. Accordingly, for $h(\mathbf{X}) = \mathbf{A} \text{alr}(\mathbf{X})$ we can derive the previous density function in terms of $h(\mathbf{X})$. It is defined on the simplex and also expressed with respect to the Lebesgue measure λ ,

$$f(\mathbf{x}) = \frac{2(2\pi)^{-(D-1)/2} |\mathbf{Y}|^{-1/2}}{\sqrt{D} \prod_{i=1}^D x_i} \exp\left(-\frac{1}{2} (h(\mathbf{x}) - \boldsymbol{\xi})' \mathbf{Y}^{-1} (h(\mathbf{x}) - \boldsymbol{\xi})\right) \Phi(\boldsymbol{\varrho}' \mathbf{v}^{-1} (h(\mathbf{x}) - \boldsymbol{\xi})), \quad (8)$$

where $\mathbf{v}$ stands for the square root of the diagonal matrix formed from $\mathbf{Y}$. The relationship between the parameters of both densities is

$$\boldsymbol{\xi} = \mathbf{A}\boldsymbol{\mu}, \quad \mathbf{Y} = \mathbf{A}\boldsymbol{\Sigma}(\mathbf{A})', \quad \boldsymbol{\varrho} = \mathbf{v}(\mathbf{A}^{-1})' \boldsymbol{\omega}^{-1} \boldsymbol{\alpha} \quad (9)$$

Both densities (7) and (8) define exactly the same probability law on S^D and are defined with respect to the Lebesgue measure λ . Using the relationship (2), it is easy to express it with respect to the Aitchison measure λ_a as

$$f_a(\mathbf{x}) = 2(2\pi)^{-(D-1)/2} |\mathbf{Y}|^{-1/2} \exp\left(-\frac{1}{2} (h(\mathbf{x}) - \boldsymbol{\xi})' \mathbf{Y}^{-1} (h(\mathbf{x}) - \boldsymbol{\xi})\right) \Phi(\boldsymbol{\varrho}' \mathbf{v}^{-1} (h(\mathbf{x}) - \boldsymbol{\xi})); \quad (10)$$

here the subindex a is only used to remind that the density is expressed with respect to λ_a . Mateu-Figueras and Pawlowsky-Glahn (2007) define the logistic skew-normal model using this density and call it the *skew-normal distribution on the simplex* by analogy to the normal on the simplex law defined using the same strategy (Mateu-Figueras et al. 2013). Even though this change of measure gives us the same law of probability, it produces changes in some characteristic values of the distribution. An interested reader can find a detailed explanation in Mateu-Figueras and Pawlowsky-Glahn (2007) and Mateu-Figueras et al. (2013). If we want to study properties of the distribution directly on the simplex, it is better to use the density with respect to the Aitchison measure because it is compatible with the simplex space structure. Moreover, the Aitchison measure enables further generalization of the logistic skew-normal distribution, if parts of the random composition are weighted, e.g., according to measurement prevision (Egozcue and Pawlowsky-Glahn 2016; Talská et al. 2020). However, for computation of probability of an event we have to use the density with respect to the Lebesgue measure in order to compute the integrals.

In Fig. 1 we present ternary diagrams with isodensity curves for two logistic skew-normal densities with respect

Additive Logistic Skew-Normal Distribution, Fig. 1 In solid line, isodensity curves of two logistic skew-normal in S^3 with: (a) $\xi = (-0.05, -0.08)$, $\Upsilon = \begin{pmatrix} 0.2 & -0.5 \\ -0.5 & 1.5 \end{pmatrix}$, $\varrho = (-5, 5)$; (b) $\xi = (1.5, 0.5)$, $\Upsilon = Id$,

$\varrho = (1.5, 2)$. In dashed-dotted line, the isodensity curves for the corresponding logistic normal model obtained with $\varrho = (0, 0)$

to the Aitchison measure. We can compare it with the corresponding logistic normal density obtained by taking $\alpha = 0$. Observe that using the logistic skew-normal models, we will be able to capture more forms of variability besides the typical arc-shape or rounded-shape forms of the logistic normal model.

Key Properties

Using the linear transformation property of the multivariate sn distribution, it is easy to prove the closure under perturbation, power transformation and subcomposition of the logistic skew-normal family of distributions. We list here the main properties using the density in terms of the logratio representation $h(\mathbf{x})$ with respect to a generic orthonormal basis, but the density in terms of the alr($\mathbf{x}$) could also be used. An interested reader can find a detailed proof of each property in Mateu-Figueras and Pawłowsky-Glahn (2007) and Mateu-Figueras et al. (2013).

Property 1 (Closure Under $\oplus$ and $\odot$). Let $\mathbf{X} \sim \mathcal{SN}_S^D(\xi, \Upsilon, \varrho)$ be a random composition, $\mathbf{a} \in S^D$ and $b \in \mathbb{R}$. Then, the D -part random composition $\mathbf{X}^* = \mathbf{a} \oplus (b \odot \mathbf{X}) \sim \mathcal{SN}_S^D(h(\mathbf{a}) + b\xi, b^2\Upsilon, \varrho)$.

From this property and using the density function with respect to the Aitchison measure λ_a we obtain the invariance under perturbation operation, i.e., $f_a(\mathbf{a} \oplus \mathbf{x}) = f_a(\mathbf{x})$. This has

important consequences, because when working with compositional data, it is usual to center the input data set which could be expressed as perturbation by a compositional vector (center of the distribution). However, this property would be not obtained using the density with respect to the measure λ . Accordingly, although both densities define the same probability law, this is one of differences between them.

Property 2 (Closure Under Subcomposition). Let $\mathbf{X} \sim \mathcal{SN}_S^D(\xi, \Upsilon, \varrho)$ and $\mathbf{X}_S = C(\mathbf{S}\mathbf{X})$ be a C -part random subcomposition. Then $\mathbf{X}_S \sim \mathcal{SN}_S^D(\xi_S, \Upsilon_S, \varrho_S)$ with

$$\begin{aligned} \xi_S &= \mathbf{U}^* \mathbf{S} \mathbf{U} \xi, & \Upsilon_S &= (\mathbf{U}^* \mathbf{S} \mathbf{U}) \Upsilon (\mathbf{U}^* \mathbf{S} \mathbf{U})', \\ \varrho_S &= \frac{v_S \Upsilon_S^{-1} \mathbf{B}' \varrho}{\sqrt{1 + \varrho' (\mathbf{v}^{-1} \Upsilon \mathbf{v}^{-1} - \mathbf{B} \Upsilon_S^{-1} \mathbf{B}') \varrho}}, \end{aligned}$$

where $\mathbf{B} = \mathbf{v}^{-1} \Upsilon (\mathbf{U}' \mathbf{S}' \mathbf{U}^*)$, v_S and $\mathbf{v}$ are the squared roots of the diagonal matrices formed by Υ_S and Υ , respectively. Matrices $\mathbf{U}$ and $\mathbf{U}^*$ contain in columns the clr representation of the corresponding orthonormal basis in S^D and S^C .

The center of a random composition $\mathbf{X}$ plays the role of the expected value for a real random vector (Pawłowsky-Glahn et al. 2015). Mateu-Figueras et al. (2013) show that this center can be expressed as the expected value using the density function with respect to λ_a ; for this reason it is denoted $E_a(\mathbf{X})$.

Property 3 (Location). Let $\mathbf{X} \sim \mathcal{SN}_S^D(\xi, \Upsilon, \varrho)$, then the expected value with respect to the measure λ_a is $E_a(\mathbf{X}) = h^{-1}(\beta)$ with $\beta = \xi + \mathbf{v}\theta\sqrt{2/\pi}$, where $\mathbf{v}$ stands for the squared root of the diagonal matrix formed by Υ and θ is as (5) but using parameters ξ , Υ and ϱ .

The expected value with respect to the Lebesgue measure corresponds to the standard expected value for real random vectors. For a logistic skew-normal random composition, there is no closed form for this value, although it exists. The reason is that the corresponding integral it is not reducible to any simple form and numerical integration should be used. Nevertheless, for random compositions, the use of $E_a(\mathbf{X})$ is recommended with the same arguments as, when working with a compositional data set, the center (the geometric mean) is used instead of the arithmetic mean.

Variability of random compositions can be measured with the metric variance, also called the total variance (Aitchison 1986).

Property 4 (Metric Variance). Let $\mathbf{X} \sim \mathcal{SN}_S^D(\xi, \Upsilon, \varrho)$, then the metric variance of $\mathbf{X}$ is $\text{Mvar}(\mathbf{X}) = \text{trace}(\Upsilon - (2/\pi)\mathbf{v}\theta\theta'\mathbf{v})$, where $\mathbf{v}$ stands for the squared root of the diagonal matrix formed by Υ and θ is as (5) but using parameters ξ , Υ , and ϱ .

Given a compositional data set, the parameters of the logistic skew-normal models can be estimated using the ML method based on the logratio representation of the data set. These estimates cannot be expressed in analytic form and numerical methods have to be used to compute them. If we change the logratio representation, the estimates will be related thought the corresponding transformation matrix $\mathbf{A}$ as we do in (9), the only deviations will be due to the numerical nature of the procedure. Thus, the estimates are invariant under the choice of the logratio representation. The logistic normal model is obtained when $\varrho = \mathbf{0}$ and, consequently, a likelihood ratio test can be used to decide if a logistic skew-normal model provides a significantly better fit.

Finally, given a compositional data set, we can validate the assumption of the logistic skew-normality via testing for multivariate skew-normality of the olr coordinate representation using a proper goodness-of-fit test. One possibility is to apply a goodness-of-fit test for the underlying χ^2 distribution with $D - 1$ degrees of freedom of the random variable $\mathbf{Z}$ (6) using an olr coordinate representation and the corresponding parameter estimates.

Application to Geochemical Data

For demonstration of fitting the skew-normal distribution on the simplex to real-world geochemical data, we use the Kola data resulting from a large geochemical mapping in the Kola peninsula of Northern Europe (Reimann et al. 1998). In total,

Additive Logistic Skew-Normal Distribution, Fig. 2 Subcomposition (Al, Si, K) of the *bhorizon* data set and the fitted isodensity curves for the logistic skew-normal model

approximately 600 soil samples were taken and analyzed for more than 50 chemical elements. The three major lithogenic elements Al, Si, and K from the *bhorizon* data set (Filzmoser 2020) are used, filtered from outlying observations (Filzmoser and Hron 2008). Using the particular olr representation $(\sqrt{1/6} \ln((x_1 x_2)/x_3^2), \sqrt{1/2} \ln(x_1/x_2))$ and the Rpackage *sn*, the following estimated parameters are obtained: $\hat{\xi} = (0.127, 1.156)$, $\hat{\Upsilon} = \begin{pmatrix} 0.332 & -0.139 \\ -0.139 & 0.074 \end{pmatrix}$ and $\hat{\varrho} = (-2.658, -0.928)$. Each marginal of the two-dimensional logratio data set exhibits a slight skewness that the skew-normal model can capture. The values of the estimated parameters depend on the particular logratio representation we use but the final model on S^3 is invariant under this choice. The fitted isodensity curves on S^3 for these three-part compositions are displayed in Fig. 2.

Summary

In the chapter the logistic skew normal model, a follower of the additive logistic skew normal distribution compatible with the algebraic-geometric structure of the simplex, was presented as a general tool for distributional modeling of compositional data in geosciences. It is flexible enough to model data coming from a wide range of applications and to provide a sensible alternative to the well-known Dirichlet distribution

which is not fully compatible with the logratio approach (Pawlowsky-Glahn et al. 2015).

Agterberg, Frits

Qiuming Cheng

School of Earth Science and Engineering, Sun Yat-Sen University, Zhuhai, China

State Key Lab of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, China

Fig. 1 Photo of Frits Agterberg taken in China University of Geosciences, Beijing, in November 2017

Biography

Frederik Pieter (Frits) Agterberg was born in 1936 in Utrecht, the Netherlands. He studied geology and geophysics at Utrecht University, obtaining B.Sc. (1957), M.Sc. (1959), and Ph.D. (1961). These three degrees were obtained “cum laude” (with distinction). After a 1-year Wisconsin Alumni Research Foundation postdoctorate fellowship at the University of Wisconsin, he joined the Geological Survey of Canada in 1962, initially as petrological statistician working on the Canadian contribution to the International Upper Mantle Project. Later, he formed and headed the Geomathematics Section of the Geological Survey of Canada in Ottawa (1971–1996).

He has made a major contribution to the geomathematical literature in numerous areas, often as the first to explore new applications and methods, and always with mathematical rigor blended with practical examples. The major research

areas include statistical frequency distributions applied to geoscience data, mineral-resources quantitative assessment, stratigraphic analysis and timescales, and fractal and multi-fractal modeling. As one of the founders of the International Association for Mathematical Geosciences (IAMG). Frits Agterberg, in his association with the IAMG, has been a key figure in its ongoing success and is widely recognized as one of the fathers of mathematical geology.

Agterberg has authored or coauthored over 350 scientific journal articles and books, including *Computer Programs for Mineral Exploration* published in 1989 by Science (Agterberg 1989), which has become a routinely used computer program for mineral resources assessments worldwide. The books he had published include the textbook *Geomathematics: Mathematical Background and Geo-Science Applications*, published in 1974 by Elsevier with approximately 10,000 copies sold worldwide (Agterberg 1974), the monograph *Automated Stratigraphic Correlation*, published in 1990 by Elsevier (Agterberg 1990), and the textbook *Geomathematics: Theoretical Foundations, Applications and Future Developments*, published in 2014 by Springer (Agterberg 2014). He has edited or coedited seven other books and many special issues in scientific journals.

Frits Agterberg received several prestigious awards and recognitions, including the third W.C. Krumbein medalist of the International Association for Mathematical Geology in 1978, Best Paper Awards for articles in the journal *Computers & Geosciences* for 1978, 1979, and 1982, correspondent member of the Royal Dutch Academy of Sciences in 1981, and as Honorary Professor of the China University of Geosciences in 1987. A newly discovered fossil, *Adercotrima agterbergi*, was named after him to recognize his contributions to quantitative stratigraphy.

Since 1968, he was associated with the University of Ottawa, where he has taught an undergraduate course on “Statistics in Geology” for 25 years and served as a supervisor for undergraduate and graduate students. Several of his former students now occupy prominent positions in the universities, government organizations, and mining industry in Canada and abroad. Other academic positions included being Distinguished Visiting Research Scientist at the Kansas Geological Survey of the University of Kansas (1969–1970), Adjunct Professor at Syracuse University (1977–1981), Esso Distinguished Lecturer for the Australian Mineral Resource Foundation, University of Sydney (August–November 1980), and Adjunct Research Professor, Department of Mathematics, Carleton University, Ottawa (1986–1994). Since 2000, he has served as a guest and distinguished professor at China

University of Geosciences (CUG) both in Beijing and Wuhan, where he has co-supervised a dozen Ph.D. students with his former student Professor Qiuming Cheng at York University.

Agterberg has lectured in more than 40 short courses worldwide, including several lectures delivered when he was named IAMG Distinguished Lecturer in 2004. From 1979 to 1985, he was leader of the International Geological Correlation Programme’s Project (IGCP) on “Quantitative Stratigraphic Correlation Techniques.” He has served on numerous committees, editorial boards, and councils of national and international organizations. For example, he served as an associate editor of several journals, including the *Canadian Journal of Earth Sciences*, the *Bulletin of the Canadian Institute of Mining and Metallurgy*, *Mathematical Geosciences*, *Computers & Geosciences*, and *Natural Resources Research*, the president of IAMG from 2004 to 2008, and general secretary of IAMG from 2012 to 2016. He chaired the Quantitative Stratigraphy Committee of the International Stratigraphic Commission (ICS), which is part of the International Union of Geological Sciences (IUGS).

In 1996, Frits Agterberg commenced a phased retirement from the Geological Survey of Canada to work as part-time independent geomathematical consultant for the industry. He continues to teach and supervise graduate students at the University of Ottawa. In November of 2017, his Chinese students and friends organized a workshop with a party on the CUGB campus for celebrating his 81st birthday and his contributions to Chinese Mathematical Geosciences. Now he is still tirelessly working on scientific publications, including coediting a large volume of the *Encyclopedia of Mathematical Geosciences*, which includes several hundred international scientists working on over 300 separate articles on different topics of mathematical geosciences.

Fig. 1 John Aitchison, courtesy of Prof. Bacon-Shone

Biography

John Aitchison was born in East Linton, East Lothian, Scotland, on July 22, 1926, and passed away in Glasgow on December 23, 2016.

John first studied mathematics at the University of Edinburgh, where he received his MA, before attending Cambridge on a scholarship, where he initially studied mathematics, before a course from Frank Anscombe diverted him to Statistics. He started his career as a statistician in the Department of Applied Economics at the University of Cambridge, where he wrote his first classic text on the lognormal distribution with Alan Brown (Aitchison and Brown 1957). This book already showed the importance of accounting for restricted sample spaces by transformation or using non-Euclidean distance metrics. He then returned to Scotland, where he was a Lecturer in Statistics in the University of Glasgow. After 5 years at the University of Liverpool, he returned to Glasgow to become Titular Professor of Statistics and Mitchell Lecturer in Statistics and write his second classic book on statistical prediction analysis (Aitchison and Dunsmore 1975). Then John took a big step into the unknown as Professor of Statistics at the University of Hong Kong. During his time in Hong Kong, John presented his seminal paper on statistical compositional data analysis (Aitchison 1982) as a read paper to the Royal Statistical Society in

London, for which he later received the Guy Medal in Silver. This influential paper (over 5000 citations) finally solved Pearson's problem of spurious correlation (Pearson 1897), which Chayes (Chayes 1960) had linked to compositional data. While others had used the logistic transformation for binary outcome probabilities, John alone saw the potential for modeling compositions in general by using the logistic Normal distribution. This paper developed into an essential monograph (Aitchison 1986). This book (which has received over 5000 citations) and many other influential related papers, which together revolutionized the statistical analysis of compositions, led to John receiving the William Christian Krumbein Medal of the International Association for Mathematical Geosciences in 1997 for a "distinguished career as author and researcher in the field of mathematical geology." After retirement from Hong Kong, John became Professor of Statistics in the University of Virginia, before finally returning to Glasgow.

Algebraic Reconstruction Techniques

Utkarsh Gupta and Uma Ranjan

Department of Computational and Data Sciences, Indian Institute of Science, Bengaluru, Karnataka, India

Definition

Algebraic reconstruction techniques (ART) were initially proposed for radiology and medical applications but have been extensively used to study various seismological phenomena (Del Pino 1985; Peterson et al. 1985). These algorithms are based on iterative reconstruction techniques and efficiently help invert matrices of large dimensions, taking advantage of the sparse nature of the matrices. These methods gained popularity due to the fact that they were able to handle various data geometries with irregular sampling and limited projection angle (Peterson et al. 1985). In addition, these techniques

are relatively more straightforward to implement compared to transform methods described by Scudder (Scudder 1978).

This entry describes fundamental principles and derivations of ART along with various modifications to ART, namely simultaneous iterative reconstructive technique (SIRT) and simultaneous algebraic reconstructive technique (SART).

Tomographic Projection Model

In iterative reconstruction techniques, one starts by discretizing the problem, as shown in the Fig. 1. We achieve discretization by superimposing a square grid on the image $g(x, y)$; we assume that each square grid cell holds a constant value denoted by g_j (subscript j denotes the j^{th} cell), and N represents the total number of cells. In addition, a ray denotes a line in the $x - y$ plane, and p_i represents the ray sum (also referred as line-integral) along i^{th} ray as shown in Fig. 1. Relation between g'_j s and p'_i s can be expressed as in Eq. 1.

$$\sum_{j=1}^N a_{ij} g_j = p_i, \quad i = 1, 2, \dots, M \quad (1)$$

where M represents the total number of rays across all the projection direction, and a_{ij} represents the weight factor which is assigned for j^{th} cell and i^{th} ray. Eq. 1 represents a large set of linear equations that needs to be inverted to determine the unknowns g'_j s.

For small values of N and M , conventional linear algebra methods like matrix inversion to determine the unknowns g'_j s

can be applied. But, in almost all the practical scenarios, values of N and M are quite large. For example, for the image of dimension 256×256 , then the value of N is as large as 65,000. For real scenarios, M 's magnitude follows the same order as of N . Direct matrix inversion is often impossible even for cases where values of N and M are small due to measurement noise in the projection data or the cases when $M < N$. In all such cases, we depend upon simple least square method. These least square-based methods are not applicable for real scenarios as M and N will be huge.

Therefore, in situations where conventional linear algebra fails to achieve the desired solution, algebraic reconstruction techniques (ART) comes into picture.

ART Algorithm

ART algorithm is based on *Methods of Projections*, proposed by Kaczmarz (1937) (hence sometimes referred to as Kaczmarz method). Eq. 1 can be unrolled as set of linear equations as follows:

$$\begin{aligned} a_{11}g_1 + a_{12}g_2 + a_{13}g_3 + \dots + a_{1N}g_N &= p_1, \\ a_{21}g_1 + a_{22}g_2 + a_{23}g_3 + \dots + a_{2N}g_N &= p_2, \\ &\vdots \\ a_{M1}g_1 + a_{M2}g_2 + a_{M3}g_3 + \dots + a_{MN}g_N &= p_M. \end{aligned} \quad (2)$$

Further, we will represent an image $g(x, y)$ as $\vec{g} = [g_1, g_2, g_3, \dots, g_N]$ which is a N -dimensional vector of unknowns g'_j s in a N -dimensional Euclidean space. Each sub-equation in Eq. 2 represents an individual hyperplane.

Algebraic Reconstruction

Techniques, Fig. 1 Illustration of tomographic projection process, with a_{ij} representing the weight contribution for j^{th} pixel and corresponding i^{th} ray

A unique solution will exist only when all the M hyperplanes intersect at a single point.

For better understanding and visualization, we explain the algorithm in two-dimensional Euclidean space with two unknowns g_1 and g_2 . These unknowns satisfy the following equations:

$$\begin{aligned} a_{11}g_1 + a_{12}g_2 &= p_1, \\ a_{21}g_1 + a_{22}g_2 &= p_2. \end{aligned} \quad (3)$$

Sub-equations in Eq. 3 represent the equations of 2D-lines, and the same is graphically shown in Fig. 2. In order to, iteratively solve the pair of linear equations (Eq. 3), we start with an initial guess $\vec{g}^0$, which is projected perpendicularly onto the first equation resulting in $\vec{g}^1$, then reprojecting the resulting point $\left(\vec{g}^1\right)$ onto the second equation and then back projecting onto the first line and so on. If a unique solution exists, the system will always converge to the solution (which in this case is represented as $\vec{g}^s$ in Fig. 2).

We can extend the same process described for solving a pair of linear equations to a large set of linear equations. The method begins with an initial guess represented by vector $\vec{g}^0 = [g_1^0, g_2^0, g_3^0, \dots, g_N^0]$. In most of the computational implementations, $\vec{g}^0$ is represented as a $\vec{0}$ vector. The initial guess is projected onto the first hyperplane of Eq. 2 giving $\vec{g}^1$. Thereafter, $\vec{g}^1$ is projected onto the second hyperplane of Eq. 2 to yield $\vec{g}^2$ and so on. When $\vec{g}^{(i-1)}$ is projected onto i^{th}

Algebraic Reconstruction Techniques, Fig. 2 The Kaczmarz method of solving algebraic equations is illustrated for the case of two unknowns. It begins with some arbitrary initial guesses and then projects onto the line corresponding to the first equation. The resulting point is now projected onto the line representing the second equation. If there are only two equations, this process is continued back and forth, until convergence is achieved. [Modified from Kak and Slaney (2001)]

hyperplane resulting in $\overrightarrow{g^{(i)}}$, this operation can be mathematically expressed as:

$$\overrightarrow{g^{(i)}} = g^{(i-1)} - \frac{\left(\overrightarrow{g^{(i-1)}} \cdot \overrightarrow{a_i} - p_i\right)}{\left(\overrightarrow{a_i} \cdot \overrightarrow{a_i}\right)} \overrightarrow{a_i} \quad (4)$$

where $(\vec{a_i} \cdot \vec{a_i})$ represents the scalar product operation and $\vec{a_i} = [a_{i1}, a_{i2}, a_{i3} \dots a_{iN}]$. Eq. 4 represents the vectorized update equation for the ART algorithm. Next section covers the derivation for Eq. 4. Vector form of the first hyperplane in Eq. 2 can be written as:

$$\vec{a}_1 \cdot \vec{g} = p_1 \quad (5)$$

where the normal vector to the hyperplane is given by $\vec{a_1} = [a_{11}, a_{12}, a_{13}, \dots, a_{1N}]$ (represented by $\vec{OD}$ in Fig. 3). Eq. 5 simply says that the projection of any vector $\vec{OC}$ (where C is any random point on the hyperplane) on the vector a_1 is of constant length. Unit vector along the direction of normal vector ($\vec{a_1}$) is represented by $\vec{OU}$ given by:

$$\overrightarrow{OU} = \frac{\overrightarrow{a_1}}{\sqrt{\overrightarrow{a_1} \cdot \overrightarrow{a_1}}} \quad (6)$$

Algebraic Reconstruction Techniques, Fig. 3 The hyperplane $\vec{a}_1 \cdot \vec{g} = p_1$ perpendicular to the vector $\vec{OD}$ ($\vec{a}_1$)

Also, the perpendicular distance of the hyperplane from the origin is represented by $\overrightarrow{OA}$ in Fig. 3, is given by $\overrightarrow{OC} \cdot \overrightarrow{OU}$:

$$\begin{aligned} |\overrightarrow{OA}| &= \overrightarrow{OU} \cdot \overrightarrow{OC} = \frac{1}{\sqrt{\overrightarrow{a_1} \cdot \overrightarrow{a_1}}} (\overrightarrow{a_1} \cdot \overrightarrow{OC}) \\ &= \frac{1}{\sqrt{\overrightarrow{a_1} \cdot \overrightarrow{a_1}}} (\overrightarrow{a_1} \cdot \overrightarrow{g}) = \frac{p_1}{\sqrt{\overrightarrow{a_1} \cdot \overrightarrow{a_1}}} \end{aligned} \quad (7)$$

To calculate $\overrightarrow{g}^1$, we subtract the initial guess $\overrightarrow{g}^0$ from the vector $\overrightarrow{HG}$:

$$\overrightarrow{g}^{(1)} = \overrightarrow{g}^{(0)} - \overrightarrow{HG} \quad (8)$$

where the length of the vector $\overrightarrow{HG}$ is represented by:

$$\begin{aligned} |\overrightarrow{HG}| &= |\overrightarrow{OF}| - |\overrightarrow{OA}| \\ &= \overrightarrow{g}^{(0)} \cdot \overrightarrow{OU} - |\overrightarrow{OA}| \end{aligned} \quad (9)$$

Substituting Eqs. 6 and 7 in Eq. 9, we get:

$$|\overrightarrow{HG}| = \frac{\left(\overrightarrow{g}^{(0)} \cdot \overrightarrow{a_1} - p_1 \right)}{\sqrt{\overrightarrow{a_1} \cdot \overrightarrow{a_1}}} \quad (10)$$

Since $\overrightarrow{HG}$ follows the same direction as the unit vector $\overrightarrow{OU}$, we can write:

$$\overrightarrow{HG} = |\overrightarrow{HG}| \overrightarrow{OU} = \frac{\left(\overrightarrow{g}^{(0)} \cdot \overrightarrow{a_1} - p_1 \right)}{(\overrightarrow{a_1} \cdot \overrightarrow{a_1})} \overrightarrow{a_1} \quad (11)$$

Finally substituting Eq. 11 in Eq. 8, we get:

$$\overrightarrow{g}^{(1)} = \overrightarrow{g}^{(0)} - \frac{\left(\overrightarrow{g}^{(0)} \cdot \overrightarrow{a_1} - p_1 \right)}{(\overrightarrow{a_1} \cdot \overrightarrow{a_1})} \overrightarrow{a_1} \quad (12)$$

Eq. 4 represents the generalized form of Eq. 12.

Convergence of ART Algorithm

Tanabe (1971) proved that if a unique solution $\overrightarrow{g}_s$ exists to a system of linear equations described by Eq. 2 (refer Fig. 2), then:

$$\lim_{k \rightarrow +\infty} \overrightarrow{g}^{(kM)} = \overrightarrow{g}_s \quad (13)$$

Few more comments about convergence have been presented below:

Case 1: Suppose, in Fig. 2, two lines are perpendicular to each other. In that case, it is possible to arrive at the actual solution in just two iterations following the update Eq. 4, and the convergence is independent of the choice of the initial guess.

Case 2: Suppose, in Fig. 2, two lines make a very small angle between them. In that case, we may require a significant number of iterations (k value in Eq. 13) to reach the actual solution depending upon the choice of the initial guess.

Clearly, rate of convergence of ART algorithm is directly influenced by the angles between the hyperplanes. If M hyperplanes in Eq. 2 can be made orthogonal with respect to one another, we can reach the actual solution in just one pass through the M equation (only in case a unique solution exists).

Characteristics of the Solution

Overdetermined System ($M > N$): Not an uncommon case, it is possible that we have more number of hyperplanes (M) than the number of unknowns (N) in Eq. 2, and also projection data ($p_1, p_2, \dots, p_M$) is corrupted by measurement noise. In

Algebraic Reconstruction Techniques, Fig. 4 Illustration of the case where all hyperplanes do not intersect at a single point. In such cases, iterations will continue to oscillate in the neighborhood of the intersections of the hyperplanes

such cases, no unique solution is possible (as shown in Fig. 4). In all such cases, ART iteration never converges to a unique point, but iterations will continue to oscillate in the neighborhood of the intersections of the hyperplanes (as shown in Fig. 4).

Under-determined System ($M < N$): In such cases, there is no unique solution, but in fact, there are an infinite number of solutions possible. It can be shown in such cases that ART iteration converges to a solution $\vec{g}_s$ such that $|\vec{g}^0 - \vec{g}_s|$ is minimized.

Advantages and Disadvantages of ART

The key feature of the iterative steps presented for ART algorithm here is that it is now possible to integrate the prior information about the reconstructed image $g(x, y)$. For example, if it is known that pixels of the reconstructed image cannot take a nonnegative value, then in each iteration, we can set negative components equal to zero. Similar to the above example, we can incorporate other information about the image $g(x, y)$ if known or conveyed in advance.

In applications requiring large-sized reconstructions, difficulties arise in calculation, storage, and efficient retrieval of weight coefficients a_{ij} . In most of the ART implementations, these weights a_{ij} exactly represent the length of the intersection of the i^{th} ray with the j^{th} pixel. It should be noted that line-length is not the only way to describe the distribution of weights; various physics-based concepts like attenuation and point spread function can also be incorporated.

Eq. 4 represents the vectorized update equation for the ART algorithm. Below we describe the ART algorithm as the gray levels/pixel (g_j) wise update equation:

$$g_j^{(i)} = g_j^{(i-1)} + \frac{(p_i - q_i) \vec{a}_{ij}}{\sum_{k=1}^N a_{ik}^2} \vec{a}_{ij} \quad (14)$$

where

$$q_i = \vec{g}^{(i-1)} \cdot \vec{a}_i \quad (15)$$

$$= \sum_{k=1}^N g_k^{(i-1)} a_{ik} \quad (16)$$

These equations represent that when we project $((i-1)^{\text{th}})$ onto the i^{th} equation, the gray level of the j^{th} pixel ($g_j^{(i-1)}$) is corrected by a factor of $\Delta g_j^{(i)}$ where:

$$\Delta g_j^{(i)} = g_j^{(i)} - g_j^{(i-1)} = \frac{p_i - q_i}{\sum_{k=1}^N a_{ik}^2} a_{ij} \quad (17)$$

Here, p_i is the measured line-integral/ray sum along the i^{th} ray, and q_i is the computed line-integral/ray sum for the same ray but using the $(i-1)^{\text{th}}$ solution for the image gray levels.

ART reconstruction, in general, suffers from salt and pepper noise which generally arises due to inconsistencies introduced while modeling the weights (a_{ik}) in the forward projection process. Due to these inconsistencies, computed ray sum (q_i in Eq. 15) is different from the measured ray sum (p_i). In the practical scenario, it is possible to reduce the effect of noise by relaxation, in which instead of updating the gray level by the factor $\Delta g_j^{(i)}$, we update it by the factor of $\alpha \Delta g_j^{(i)}$, where α is less than 1. At the same time, introducing the relaxation parameter α in the update equation leads to the slower convergence of the ART algorithm.

Finally, the update equation for the ART algorithm including the relaxation parameter α is described below:

$$g_j^{(i+1)} = g_j^{(i)} + \alpha \Delta g_j^{(i)} \quad (18)$$

$$\vec{g}^{(i+1)} = \vec{g}^{(i)} + \alpha \frac{(p_i - \vec{g}^{(i)} \cdot \vec{a}_i)}{(\vec{a}_i \cdot \vec{a}_i)} \vec{a}_i \quad (19)$$

Simultaneous Iterative Reconstructive Technique (SIRT)

Simultaneous iterative reconstructive technique (SIRT) (Gilbert 1972) is another iterative algorithm that produces a smoother and better-looking reconstructed image than those produced from the ART algorithm at the cost of slower convergence. We again compute the correction term $\Delta g_j^{(i)}$ (using Eq. 17) in the j^{th} pixel caused by i^{th} equation. But before adding the correction term to the j^{th} gray level, we calculate all the correction terms calculated from all the M equations in Eq. 2, after that, we update the gray level in the j^{th} cell by adding the average of all the obtained correction terms obtained from each equations. This concludes the one iteration of the SIRT algorithm. In the second iteration, we again start with the first equation in Eq. 2, and the process is repeated. Mathematically SIRT update equation can be represented as:

$$g_j^{(k+1)} = g_j^{(k)} + \alpha \frac{\sum_{i=1}^M \Delta g_j^{(i)}}{M} \quad (20)$$

where k represents the iteration number, M signifies number of total projection rays or total number of algebraic equations, and α represents the relaxation parameter.

Simultaneous Algebraic Reconstructive Technique (SART)

Simultaneous algebraic reconstructive technique (SART) (Andersen and Kak 1984) was designed with mainly two objectives in mind: first is to reduce the salt and pepper noise commonly found in ART-type reconstruction algorithms, and secondly to achieve good quality and numerical accuracy in only a single iteration. We will now describe the key steps involved in SART algorithm.

Modeling the Forward Projection Process

For SART-type reconstruction algorithm, we express the image $g(x, y)$ as the linear combination of N basis images ($b_j(x, y)$) weighted by real numbers $\beta_1, \beta_2, \beta_3, \dots, \beta_N$.

This can be mathematically expressed as:

$$g(x, y) \approx \hat{g}(x, y) = \sum_{j=1}^N \beta_j b_j(x, y) \quad (21)$$

$\hat{g}(x, y)$ is a discrete approximation of the actual image $g(x, y)$, and β_j 's are the finite set of numbers which completely describes the image relative to the chosen basis images ($b_j(x, y)$).

If $r_i(x, y) = 0$ is the equation of i^{th} ray, the projection operator R_j along the direction of the ray can be expressed as follows:

$$p_i = R_i g(x, y) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} g(x, y) \delta(r_i(x, y)) dx dy \quad (22)$$

Assuming the projection operator R_j as a linear operator, we have:

$$R_i \hat{g}(x, y) = \sum_{j=1}^N \beta_j R_i b_j(x, y) \quad (23)$$

In practical implementation of SART-type algorithm, we compute $R_i \hat{g}(x, y)$ using some approximations a_{ij} to reduce the computational load of the algorithm. Hence, we get:

$$\begin{aligned} p_i &= R_i g(x, y) \approx R_i \hat{g}(x, y) = \sum_{j=1}^N \beta_j R_i b_j(x, y) \\ &\approx \sum_{j=1}^N \beta_j a_{ij} \end{aligned} \quad (24)$$

$$p_i = \sum_{j=1}^N \beta_j a_{ij} \quad (25)$$

Here, a_{ij} represent the line integral of $b_j(x, y)$ along the i^{th} ray. Eq. 25 shares the same structure as Eq. 1 and is yet more generalized since β_j does not represent the image gray levels as g_j in Eq. 1. Eq. 25 and Eq. 1 are equivalent if in case image frame is divided into N identical sub-squares, and we use the basis image as described by Eq. 26.

$$b_j(x, y) = \begin{cases} 1, & \text{inside the } j^{th} \text{ pixel} \\ 0, & \text{otherwise} \end{cases} \quad (26)$$

SART algorithm provides superior reconstruction using the forward projection process described above. Accurate reconstructions are obtained using bilinear elements which are simplest higher order basis functions. It can be shown that using bilinear basis we obtain a more continuous image reconstruction than those which are obtained using pixel basis. However, computing line-integral across these bilinear basis is a computationally expensive task. Hence we approximate the overall ray integral $R_i \hat{g}(x, y)$ by finite sum involving M_i equidistant point $\{\hat{g}(s_{im})\}$ (see Fig. 5a).

$$p_i = \sum_{m=1}^{M_i} \hat{g}(s_{im}) \Delta s \quad (27)$$

$\hat{g}(s_{im})$ is determined using bilinear interpolation using the values β_j of $g(x, y)$ on the four neighboring points on the sample lattice. We get:

$$\hat{g}(s_{im}) = \sum_{j=1}^N d_{ijm} \beta_j \quad (28)$$

where d_{ijm} represents the contribution that is made by the j^{th} image to the m^{th} point on the i^{th} ray. Overall, we can approximate the line-integral p_i as the linear combination of the β_j :

$$p_i = \sum_{m=1}^{M_i} \sum_{j=1}^N d_{ijm} \beta_j \Delta s \quad (29)$$

$$p_i = \sum_{j=1}^N \sum_{m=1}^{M_i} d_{ijm} \beta_j \Delta s, 1 \leq i \leq J \quad (30)$$

$$= \sum_{j=1}^N a_{ij} \beta_j \quad (31)$$

Algebraic Reconstruction Techniques, Fig. 5 (a)

Illustration of the ray-integral equations for a set of equidistant points along a straight line cut by the circular reconstruction region.

(b) Longitudinal Hamming window for set of rays

where a_{ij} is computed as the sum of contribution from different points along the ray.

$$a_{ij} = \sum_{m=1}^{M_i} d_{ijm} \Delta s \quad (32)$$

Also, the overall weights (a_{ij}) are adjusted in such a way that $\sum_{j=1}^N a_{ij}$ is actually equal to the physical length L_j . The precise formula used for updating the β'_i 's using SART algorithm is stated as:

$$\vec{\beta}_j^{(k+1)} = \vec{\beta}_j^{(k)} + \frac{\sum_i \left[t_{ij} \frac{(\vec{p}_i - \vec{\beta}^{(k)}) \cdot \vec{a}_i}{\sum_{j=1}^N a_{ij}} \right]}{\sum_i a_{ij}} \quad (33)$$

where

$$t_{ij} = \sum_{m=1}^{M_i} h_{im} d_{ijm} \Delta s \quad (34)$$

where the summation with respect to i is over the rays intersecting the j^{th} image cell for a given projection direction. The sequence h_{im} , for $1 \leq m \leq M_i$, is a Hamming window of length M_i and length of the window varies according to the number of point M_i describing the part of ray inside the reconstruction circle.

On the whole, SART algorithm described using the update Eq. 33 results in a less noisy reconstructed image when compared to images reconstructed using ART and SIRT type algorithms.

Summary and Conclusions

This chapter covers three essential algebraic reconstruction techniques: ART, SIRT, and SART, prominent in geoscience, primarily for seismological research and application. Also, these algorithms form the basis for several other algebraic-based reconstruction techniques proposed for various tasks. For instance, C-SART (constrained simultaneous algebraic reconstruction technique) algorithm has been applied for ionospheric tomography (Hobiger et al. 2008) that has a higher convergence rate than classical SART. These algorithms, being iterative in nature, have the added advantage of requiring less computational storage along with fast convergence to the solution in case of large and sparse linear systems (Xun 1987).

Allometric Power Laws

Gabor Korvin

Earth Science Department, King Fahd University of
Petroleum and Minerals, Dhahran, Kingdom of Saudi Arabia

Definition

Allometry has its origin in biology, anatomy, and physiology; it studies the effect of body size on shape and metabolic rate, the laws of growth, and relationships between size and different measurable properties of living organisms. Its laws were first summarized by D’Arcy Thompson in 1917 and Julian Huxley in 1932 (Stevens 2009). Frequently, relationships between size and other measured quantities obey power law equations (*Allometric Power Laws*) of the form $y = kx^\alpha$ (with standard notation $y \propto x^\alpha$ or $y \sim x^\alpha$, where $\propto$ or $\sim$ denote proportionality). The exponent α is in most cases a non-integer real number, which explains the name of the discipline (allometry < Gr. *ἄλλωμετρον* = “strange scale”). APLs of the form $y \propto x^\alpha$ are also called *scaling laws*, because they are *scale-invariant*, and they arise when describing *self-similar objects*, such as earth-materials and formations on the surface and in the interior of the Earth and planets.

Introduction: Allometric Power Laws and Self-Similarity

A *power law* is a functional relationship between two quantities, and it has the form $y = kx^\alpha$ (with standard notation $y \propto x^\alpha$ or $y \sim x^\alpha$, where $\propto$ or $\sim$ denote proportionality). Famous power laws are the *allometric power laws* (APLs in what follows), originally used to express relationships between body size and biological variables (Stevens 2009), such as the empirical rule that metabolic rate q_0 is proportional to body mass M raised to the $(3/4)^{\text{th}}$ power: $q_0 \propto M^{3/4}$, or that heart

rate τ is inversely proportional to the $(1/4)^{\text{th}}$ power of M : $\tau \propto M^{-1/4}$. Dimensional considerations would suggest a metabolic rate proportional to the surface area available for energy transfer, so one would expect that metabolic rates of similar organism should scale as $q_0 \propto M^{2/3}$ rather than the empirical “ $M^{0.75}$ ” law, and the very name of such laws (allometry < Gr. *ἄλλωμετρον* = “strange scale”) expresses the fact that most observed APL exponents are “strange,” in the sense that their values usually cannot be derived from physical principles or dimensional analysis (Korvin 1992: 233).

APLs of the form $y = kx^\alpha$ (where both sides are positive) can be written, taking logarithm, as $\log y = \alpha \log x + \log k$ or $\ln y = \alpha \ln x + \ln k$ that is they show up as straight lines when plotted on double-logarithmic axes, and the *scaling exponent* is obtained from the slope.

APLs are *scale invariant*. Given an APL $f(x) = k \cdot x^\alpha$, multiplying the argument x by a factor λ causes only a proportionate change in the function itself: $(\lambda x) = k(\lambda x)^\alpha = \lambda^\alpha f(x) \propto f(x)$.

The frequent occurrence of such APLs in Geosciences (see Table 1) which connect two measured properties of a geologic object (as, e.g., perimeter and area of islands, width and depth of rivers, etc.) is a consequence of the *similarity* of all geological objects of the same kind (as, e.g., all mountains, all islands, all sea coasts, all meandering rivers), or it arises because of their *self-similarity*, that is the (statistical) similarity of their parts observed at different scales (Korvin 1992: 4–5).

Consider, as an example, the relation between wavelengths L and widths W of meanders of different size (Fig. 1), and assume there exists a functional relation $W = W(L)$ (Eq. 1) between them. Consider three pieces of the same meander, or from different meanders, with wavelengths $L_1 > L_2 > L_3$. Because of the similarity of meanders, one has for any two wavelengths L_a and L_b that $\frac{W(L_a)}{W(L_b)} = f\left(\frac{L_a}{L_b}\right)$ with a yet unknown function $f(x)$, i.e., $W(L_a) = W(L_b)f\left(\frac{L_a}{L_b}\right)$ (Eq. 2), in particular $W_1 = W_3f\left(\frac{L_1}{L_3}\right)$; $W_1 = W_2f\left(\frac{L_1}{L_2}\right)$; $W_2 = W_3f\left(\frac{L_2}{L_3}\right)$ (Eqs. 3 a-c). Combining Eqs. (3. a, b, c) yields $\left(\frac{L_1}{L_3}\right) = f\left(\frac{L_1}{L_2}\right)f\left(\frac{L_2}{L_3}\right)$, that is, letting $\frac{L_1}{L_2} = a$, $\frac{L_2}{L_3} = b$ we see that for all $a, b > 0$ the unknown function $f(x)$ satisfies $f(a \cdot b) = f(a) \cdot f(b)$ (Eq. 4). This is Cauchy’s functional equation (Aczél & Dhombres 1989; Korvin 1992: 73–76) whose only continuous solution (apart from $f(x) \equiv 0$) is $f(x) = x^\alpha$ for some real number α . Writing up Eq. 2 for the case $L_a = L$, $L_b = 1$, $W(1) = w$ we get an APL: $W = wL^\alpha$ (Eq. 5) connecting meander width with wavelength (Korvin 1992: 6). *Note that the value of exponent α cannot be found from scaling arguments!*

Allometric Power Laws, Table 1 Some empirically found APLs in Geosciences (the exponent b is different in each case)

#	Name of the law	Equation	Meaning of the constants	Authors	Discussion of the law
1	Cloud areas and perimeters	$P \propto A^{\frac{D}{2}}$ (Eq. 6)	P = cloud perimeter A = cloud area, $D = 1.35 \pm 0.05$	Lovejoy (1982)	Korvin (1992): 62
2	Destruction of basaltic bodies by high velocity impacts	$M(<s) \propto s^b$ or $N(>m) \propto m^{-b}$ (Eqs. 7a, b)	$M(<s)$ = total mass of fragments of size $< s$ $N(>m)$ = total # of fragments of mass larger than m	Fujiwara et al. (1977)	Korvin (1992): 203
3	Drainage area vs. channel length	$L \propto A_d^{0.5}$ (Eq. 8)	L = channel length A_d = drainage area	Hack (1957)	Korvin (1992): 6
4	Grain size distribution in sedimentary rock	$N(r) \propto \left(\frac{r}{r_0}\right)^{-b}$ (Eq. 9)	$N(r)$ = # of grains longer than r , r_0 reference length	Johnson and Kotz (1970)	Korvin (1992): 203
5	Horton's law of stream numbers	$N_\omega = R_B^{\Omega-\omega}$ (Eq. 10)	N_ω = # of streams of order ω , Ω is the order of the basin, R_B is the bifurcation ratio	Horton (1945)	Scheidegger (1968)
6	Meander width and channel width vs. channel depth	$W_c = 6.8h^{1.54}$ $W_m = 7.44W_c^{1.01}$ (Eqs. 11. a, b)	W_m meander width, W_c channel width, h Channel depth (feet)	Lorenz et al. (1985)	Korvin (1992): 1–3
7	Number of clusters of entrapped oil particles in rock	$n_s \propto s^{-b}$ (Eq. 12)	n_s = # of clusters s = # of oil droplets in a cluster	Sherwood (1986)	Korvin (1992): 193–195
8	Porosity vs. grain radius and eff. hydraulic radius for sandstone and graywacke	$\Phi = 0.5 \left(\frac{r_{\text{grain}}}{r_{\text{eff}}}\right)^{-0.25}$ (Eq. 13)	Φ porosity, r_{grain} grain radius, r_{eff} effective hydraulic radius	Pape et al. (1984)	Korvin (1992): 288
9	Porosity vs. pore-size for sandstone	$\Phi = \left(\frac{l_1}{l_2}\right)^b$ (Eq. 14)	Φ porosity, l_1 and l_2 smallest and largest pore size	Katz and Thompson (1985)	Korvin (1992): 286–287
10	Rivers' width vs. depth (for sinuosity > 1.7)	$W_c \propto h^{1.54}$ (Eq. 15)	W_c bankfull width, h bankfull depth	Leeder (1973)	Korvin (1992): 1
11	Size distribution of caves	$N(l) \propto \left(\frac{l}{l_0}\right)^{-b}$ (Eq. 16)	$N(l)$ # of caves longer than l , l_0 reference length	Curl (1986)	Korvin (1992): 197
12	Size distribution of islands	$Prob(A > a) \propto a^{-b}$ (Eq. 17)	A , a areas	Korčák (1940)	Korvin (1992): 191
13	Undesirable porosity in concrete	$\Phi = \left(\frac{l_1}{l_2}\right)^{1/5}$ (Eq. 18)	Φ porosity, l_1 and l_2 smallest and largest grain size	Caquot (1937)	Korvin (1992): 14

Allometric Power Laws,

Fig. 1 Derivation of the APL between meander width W and wavelength L . (From Korvin 1992: 5)

Several kinds of phenomena can produce, or explain, the observed APLs in earth-processes, earth-formations, and geomaterials. If an earth-process is observed to similarly behave across a range of spatial and/or temporal scales, the created formation usually becomes self-similar, and thus described by APLs. Deterministic chaos, self-organized

criticality (SOC, Hergarten 2002), critical phenomena (as rock fragmentation and failure, Turcotte 1986) are also associated with APLs. Other relevant models leading to APLs include (Mitzenmacher 2004): preferential attachment (applied in transportation geography, geomicrobiology, soil science, hydrology, and geomorphology); minimization of

costs, entropy, etc. (applicable to channel networks and drainage basins); multiplicative cascade models (used in meteorology, soil physics, geochemistry); and DLA (Diffusion Limited Aggregation, Korvin 1992: 349–366, used to model the growth of drainage networks, escarpments, eroded plateaus). However, as we know from geomorphology, similar landforms and other earth-formations might arise through quite different processes. This is the principle of *equifinality* (Bertalanffy 1968): same or similar outcomes can be produced by different processes, and thus there is no way to reconstruct the formative mechanism from the APLs obeyed by the resulting geologic objects.

Examples for Allometric Power Laws in Geosciences

Some examples for APLs are compiled in Table 1. Discussion of these laws and references to their sources are found in Korvin (1992).

Allometric Relations with Modified Power Laws

Empirical data are sometimes better described by approximate power laws instead of the ideal APL $y = ax^k$ because of random errors in the observed values, or their systematic deviation from the power law. Such functional forms, of course, do not have *scaling symmetry* any more. Popular variants are (https://en.wikipedia.org/wiki/Power_law):

Power law with error term: $y = ax^k + \varepsilon$ (Eq. 19).

Broken power law: It is a piece-wise function consisting of one or more power laws, for two power laws, for example:

$$\left. \begin{array}{ll} y \propto x^{\alpha_1} & \text{for } x < x_{th} \\ y \propto x^{\alpha_1 - \alpha_2} x^{\alpha_2} & \text{for } x > x_{th} \end{array} \right\} \text{ (Eq. 20, the threshold } x_{th} \text{ is the cross-over).}$$

Power law with exponential cutoff: $y \propto x^\alpha e^{-\beta x}$ (Eq. 21).

Curved power law: $f(x) \propto x^{\alpha + \beta x}$ (Eq. 22).

Rigout's formula: Rigout (1984, cited in Korvin 1992: 290) described the *Richardson-Mandelbrot plot* (Mandelbrot 1982) for the length of Britain's coastline measured with resolution λ as $L(\lambda) = L_{max} \left\{ 1 + \left(\frac{\lambda}{L_0} \right)^c \right\}^{-1}$ (Eq. 23, L_0 is the *cross-over length*). This approach makes possible to describe two slopes (one seen for small, one for large λ values) on the double-logarithmic plot. The same trick was used by Pape et al. (1984, cited in Korvin 1992: 290) who studied the scaling of pore volume $\Phi(\lambda)$ with resolution λ and found $\Phi(\lambda) = \Phi_{max} \left\{ 1 + \left(\frac{0.5676\lambda}{r_{pore}} \right)^{0.6434} \right\}^{-1}$ (Eq. 24, r_{pore} is pore radius).

Allometric Power Laws for Size Distribution

From among the APLs compiled in Table 1, #7 (number of clusters of entrapped oil particles in rock), #11 (size distribution of caves), and #12 (size distribution of islands, called Korčak's law) are examples for the probability distribution (or the total number, total volume, or total mass) of geologic objects with respect to their size. While Korčak claimed that $b = 0.5$ in his law $Prob(A > a) \propto a^{-b}$ (Eq. 17), careful regression of his data gave $b = 0.48$; Mandelbrot reported $b = 0.65$ for the whole Earth with considerable variation for the different regions, for example, $b = 0.5$ was found for Africa, $b = 0.75$ for Indonesia and North America (Korvin 1992: 191; Mandelbrot 1982). Eq. (17) defines what is called in probability theory the “power law,” “hyperbolic,” or “Pareto” distribution.

The power-law probability distribution $p(x) \propto x^{-\alpha}$ has a well-defined mean over $x \in [1, \infty)$ only if $\alpha > 2$, and it has a finite *variance* only if $\alpha > 3$. For most observed power-law distributions in Geosciences, the exponents α are such that the mean is well-defined but the variance does not exist because typically the exponent falls in the range $2 < \alpha < 3$. It is important to note that for power-law distributions $p(x) = Cx^{-\alpha}$ for $x > x_{min}$ and $\alpha > 1$, the *median does exist*, and $p_{median} = 2^{1/(\alpha-1)} x_{min}$ (Eq. 25). In this case, $p(x)$ can be written in the normalized form $p(x) = \frac{\alpha-1}{\alpha x_{min}} \left(\frac{x}{x_{min}} \right)^{-\alpha}$ (Eq. 26). Its moments can also be computed: $\langle x^m \rangle = \int_{x_{min}}^{\infty} x^m p(x) dx = \frac{\alpha-1}{\alpha-1-m} x_{min}^m$ for $m < \alpha - 1$ (Eq. 27). For $m \geq \alpha - 1$, all moments diverge: in the case $\alpha \leq 2$, the mean and all higher-order moments are infinite; when $2 < \alpha < 3$, the mean exists, but the variance and higher-order moments diverge.

To avoid divergences, power-law distributions can be made more tractable with an *exponential cutoff*, i.e., by using $p(x) \propto x^{-\alpha} e^{-\lambda x}$ (Eq. 28), where the exponential decay $e^{-\lambda x}$ suppresses the power-law-like increase at large values of x . This distribution does not scale for large values of x ; but it is approximately scaling over a finite region before the cutoff (whose size is controlled with the parameter λ).

CAVEAT: The geoscientist should never forget that the straightness of the plotted line is a necessary, but not sufficient, condition for the data to follow a power-law relation, and *many non-power-law distributions will also appear as approximately straight lines on a log-log plot*. For example, *log-normal distributions* are often mistaken for power-law distributions (Clauset et al. 2009, Mitzenmacher 2004, Korvin 1989). Equations and practical advice for fitting a power-law distribution, estimating the uncertainty in the fitted parameters, calculating the p -value for the fitted power-law model can be found in Clauset et al. (2009) and its very useful “Companion paper” (<https://aaronclauset.github.io/powerlaws/>) which provides usable code (in Matlab, Python, R and C++) for the estimation and testing routines.

Concluding Remarks: The Power of Allometric Power Laws

As two case histories will show, APLs are a useful tool in the hand of the practicing or theoretical geoscientist. Perhaps the most beautiful *practical* use of APLs was made in 1985, in a reserve estimation project. J.C. Lorenz and co-workers at the Sandia National Laboratories, Albuquerque, tried to estimate the maximum width of the meanders of an ancient fluvial system (that is the present-day *reservoir extension*) using only the depths of paleostreams measured in wells (their work is reviewed, and referenced, in Korvin 1992: 1–3). Actually, they only used core and log data from a *single well*. They identified 49 fining-upward sand bodies from the meandering fluvial environment of the Mesaverde group, from the histogram of their preserved thicknesses estimated the maximal paleo-channel depth as 3–4 m (10–13 ft). To take into account postdepositional compaction of sand into sandstone, they increased this thickness by 11% which gave 3.3–4.4 m (11–13 ft) depth at the time of deposition. Then they substituted the decompacted channel depth into the empirical APL $W_c = 6.8h^{1.54}$ Eq. (11a, see Law #6 in Table 1). The formula gave an estimated channel width $W_c = 45 - 67m(150 - 220ft)$, plugging this into the APL $W_m = 7.44W_c^{1.01}$ (Eq. 11.b) yielded the predicted meander belt width $W_c = 350 - 520m(1,100 - 1,700ft)$.

Many empirical laws of the physics of sedimentary rock describe some physical property of the rock as a *power of porosity*, as, e.g., the conductivity σ of fluid-filled rock satisfies $\sigma \propto \Phi^{m_1}$ (Archie's law, Eq. 29), for some rocks and some porosity ranges the permeability k satisfies $k \propto \Phi^{m_2}$ (Eq. 30). Such power laws are not considered *allometric power laws* (APL) because while the dependence is power-like, the measured quantity is a property of the whole rock, and not of its size. To find a heuristic explanation of such empirical findings, one must keep in mind that very often we can assume hierarchical (or fractal) structures and processes, and hidden APLs lying behind such power law-like behavior. Consider, e.g., the empirically observed $k \propto \Phi^{m_2}$ relation (Eq. 30) and try to explain it by scaling arguments (Korvin 1992: 292–294). According to the Kozeny-Carman relation: $k = \frac{1}{b} \Phi^3 \cdot \frac{1}{S_{spec}^2} \cdot \frac{1}{\tau^2}$ (Eq. 31), where k is permeability, Φ porosity, S_{spec} specific surface of the pore space, τ tortuosity, and b a constant depending on the shape of the pore-throats available for the flow. Denote by ε the smallest pore size, and consider a piece of rock of fixed size $R, \gg \varepsilon$. If the total pore volume in an R -sized rock scales with fractal dimension D_p , then $\Phi_{total} \propto \left(\frac{R}{\varepsilon}\right)^{D_p}$, and porosity scales with ε as $\Phi \sim \frac{\Phi_{total}}{R^3} \propto \left(\frac{R}{\varepsilon}\right)^{D_p} \cdot R^{-3} = \frac{R^{D_p-3}}{\varepsilon^{D_p}} \propto \varepsilon^{m_4}$ (Eq. 32, in this heuristic consideration $m_1, m_2, \dots$ are the corresponding exponents). If the pore surface has fractal dimension D_s , the specific surface of a piece of rock of size R scales as $S_{spec} \propto \left(\frac{R}{\varepsilon}\right)^{D_s} / R^3 = \frac{R^{D_s-3}}{\varepsilon^{D_s}} \propto \varepsilon^{m_5}$ (Eq. 33). Next, consider tortuosity $\tau (= \text{hydraulic path/straight line path})$ over

distance R . If R is not too great, the hydraulic path is a *planar curve*, that is its fractal dimension is $D_s - 1$ (by Mandelbrot's rule, Mandelbrot 1982: 365, Korvin 1992: 125 Eq. 2.3.1.7) and its length scales as $L_{hydr} \propto \left(\frac{R}{\varepsilon}\right)^{D_s-1}$, so tortuosity satisfies $\tau = \frac{L_{hydr}}{R} \propto \left(\frac{R}{\varepsilon}\right)^{D_s-1} \cdot R^{-1} \propto \varepsilon^{m_6}$ (Eq. 34). Plugging Eqs. (32, 33, 34) into the right-hand side of Eq. (31), we find that permeability also scales as a power of ε : $k \propto \varepsilon^{m_7} = (\varepsilon^{m_4})^{(m_7/m_4)} \propto \Phi^{(m_{10}/m_4)}$ (Eq. 35) ($m_4 = -D_p \approx 3$, certainly $m_4 \neq 0$) which explains the power-like relation $k \propto \Phi^{m_2}$ in (Eq. 30). Thus, fractal geometry, assumption of self-similar pores, and simple scaling arguments yield a heuristic explanation for the empirical power-law relation between porosity and permeability over a limited range of specimen and pore size. Because of the principle of *equifinality*, this – of course – is only one of the many possible explanations.

Argand Diagram

James Irving¹ and Eric P. Verrecchia²

¹Institute of Earth Sciences, University of Lausanne, Lausanne, Switzerland

²Institute of Earth Surface Dynamics, University of Lausanne, Lausanne, Switzerland

Synonyms

Argand plane; Cole-Cole plot; Complex plane; Gauss plane; Impedance diagram; Zero-pole diagram; Zero-pole plane; z-plane

Definition

The Argand diagram denotes a graphical method to plot complex numbers, expressed in the form $z = x + iy$, where (x, y) are used as coordinates and plotted on a plane with two orthogonal axes, the abscissa representing the real axis and the ordinate the imaginary axis.

Argand Diagram

The Argand diagram is a way to plot a complex number in the form of $z = x + iy$, using the ordered pair (x, y) as coordinates and where the constant i represents the imaginary unit, i.e., $\sqrt{-1}$. The Argand diagram (or plane) is therefore defined by two orthogonal axes where the abscissa refers to a real axis and the ordinate to an imaginary axis.

Historical Origin of the Argand Diagram

The family name attached to the Argand diagram designates that this geometric representation of complex numbers is credited to Swiss mathematician Jean-Robert Argand, who was born in Geneva in 1768 and died in Paris in 1822. Indeed, this graphical method has been detailed in Argand (1806). Nevertheless, Howarth (2017) suggested that the plot was first introduced by Caspar Wessel (1799), a Norwegian-Danish mathematician. Wessel (1745–1818) presented his work about the analytical representation of the direction of numbers to the Academy of Science in Copenhagen on March 10, 1797; this contribution was printed in 1798 and finally published in 1799. Nevertheless, Valentiner (1897), in the first preface of the French translation of Wessel's essay, noted that Carl Friedrich Gauss (1777–1855) arrived at the same idea in the same year (1799), but without citing any specific source. This remark led some researchers to refer to the Argand plane as the Gauss plane. In the same preface, Valentiner also acknowledged a British mathematician, John Wallis (1616–1703). It seems that Wallis proposed a similar approach, even earlier than Wessel, in his "Treatise of Algebra," published in London in 1685. Valentiner noted that Wessel's essay includes "a theory as complete as Argand's, and in my opinion, more correct [...]" (Valentiner, 1897, p. iii). Regarding the various synonyms for the Argand diagram, such as the complex z-plane, zero-pole diagram, or zero-pole plot, they were introduced during the twentieth century, mostly by mathematicians and geophysicists. For example, according to Howarth (2017), the concept of "complex z-plane," with z referring to $z = x + iy$, was coined by the American mathematician William Fogg Osgood at the turn of the twentieth century (Osgood 1901) and used later by engineers studying signal processing as the "zero-pole diagram" and "zero-pole plot." In geophysics, the concept of "zero-

Argand Diagram, Fig. 1 Left, representation of an imaginary number (z), and its conjugate ($\bar{z}$), as ordered pairs (x, y) , and $(x, -y)$, on an Argand diagram, respectively. The x-axis is the real axis, whereas the

y-axis refers to the imaginary axis. Right: representation of the same numbers in terms of the modulus (M) and the angle (θ) as polar coordinates (M, θ)

pole” usually refers to the z-transform of a discrete impulse response function when it reaches infinite values (Buttkus 2000).

The Argand Diagram: A Geometric Plot

The Argand diagram is a kind of Cartesian plane upon which an imaginary number, $z = x + iy$, is represented with its real part along the x-axis and its imaginary part along the y-axis. It provides a geometrical way of locating imaginary numbers (Fig. 1, left). Therefore, any complex number can be recognized by the coordinates of a unique point in the diagram according to its ordered pair (x, y) . Any complex number with a null real part ($z = 0 + iy$) will lie on the vertical imaginary axis, whereas any real number ($z = x + i0$) will lie on the real horizontal axis. The conjugate of a complex number, i.e., $\bar{z} = x - iy$, can be easily represented by its symmetric location along the real x-axis (Fig. 1, left), i.e., by the $(x, -y)$ coordinates on the Argand diagram. The distance from the origin $(0, 0)$ to a given point (x, y) on the Argand plane is known as the modulus of z (or its absolute value), and is usually denoted by r , M , or $|z|$. The modulus is easily calculated as $|z| = \sqrt{x^2 + y^2}$.

Complex numbers can also be expressed in polar form on the Argand diagram, i.e., using the modulus (M) and the angle (θ) (also called the argument $\text{Arg}(z)$) as polar coordinates, the angle (θ) being measured along the positive direction of the real x-axis. Consequently, the ordered pair (x, y) is replaced by the pair (M, θ) as illustrated in Fig. 1 (right). The ordered pair (x, y) can now be calculated as:

$$x = M \cdot \cos(\theta) \text{ and } y = M \cdot \sin(\theta) \quad (1)$$

Therefore, $z = M \cdot \cos(\theta) + i \cdot M \cdot \sin(\theta)$. Using Euler’s formulae expressing the relationship between trigonometric functions, e (Euler’s number) and i ($\sqrt{-1}$ number), i.e.,

$$\cos(\theta) = \frac{e^{i\theta} + e^{-i\theta}}{2} \text{ and } \sin(\theta) = \frac{e^{i\theta} - e^{-i\theta}}{2i} \quad (2)$$

we arrive at

$$\begin{aligned} z &= M(\cos(\theta) + i \cdot \sin(\theta)) = M \left[\frac{e^{i\theta} + e^{-i\theta}}{2} + i \cdot \frac{e^{i\theta} - e^{-i\theta}}{2i} \right] \\ &= M \cdot e^{i\theta} \end{aligned}$$

If $z = M \cdot e^{i\theta}$, then $\bar{z} = M \cdot e^{-i\theta}$. Following Eq. (1):

$$\frac{y}{x} = \frac{\sin \theta}{\cos \theta} = \tan \theta \Rightarrow \theta = \arctan\left(\frac{y}{x}\right) \quad (3)$$

Some Applications of the Argand Diagram in Geosciences

In many areas of the geosciences, complex numbers play an important role, and the Argand diagram can serve as a useful tool for data analysis. A wide range of Earth materials, for example, possess dispersive material properties, whereby the steady-state material response to a sinusoidal forcing depends on the frequency at which the forcing is applied. Due to various relaxation phenomena, both the amplitude and phase of the response will vary with frequency, meaning that the corresponding physical property, which links the response and forcing through a constitutive equation, takes the form of a complex and frequency-dependent variable in the Fourier domain. One commonly used formulation to describe such behavior is the Cole-Cole model (Cole and Cole 1941). Originally proposed to describe the relaxation behavior of the dielectric permittivity, it is given by

Argand Diagram, Fig. 2 Plot of the imaginary versus real part of the complex dielectric permittivity corresponding to the Cole-Cole model, for different values of α . Frequency was varied from 1 Hz to 10^{20} Hz, with fixed parameters $\varepsilon_\infty = 5 \text{ F.m}^{-1}$, $\varepsilon_0 = 80 \text{ F.m}^{-1}$, $\tau = 10^{-10} \text{ s}$

$$\varepsilon'(\omega) - i\varepsilon''(\omega) = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + (i\omega\tau)^\alpha} \quad (4)$$

where $\varepsilon'(\omega)$ and $\varepsilon''(\omega)$ are the real and imaginary parts of the permittivity [F.m^{-1}], ε_∞ and ε_s are the high- and low-frequency limiting values of the real part, ω is the angular frequency [s^{-1}], τ is a relaxation time constant [s], and α is a unitless time-constant distribution parameter that varies between 0 and 1. Plots on an Argand diagram of complex permittivity measurements made at different frequencies provide insight into the nature of the relaxation (Fig. 2). For instance, $\alpha = 1$ in the Cole-Cole equation describes a Debye-type relaxation response involving a single polarization mechanism, and the complex values plot along a semi-circular arc whose intersections with the real axis correspond to ε_∞ and ε_s . Lower values of α result in Argand plots with the same real-axis intersections but lower complex amplitudes, indicating a distribution of relaxations within the considered frequency range. Multiple polarization mechanisms whose relaxations are well separated in frequency may appear as more than one arc. Similar analyses using the Cole-Cole and other related models have been performed for the electrical conductivity as well as for various elastic moduli.

Argand diagrams have also proven highly useful in the context of linear time-invariant (LTI) system identification and digital filter design, for which there are many important applications in the geosciences. In the z -transform domain, the input $X(z^{-1})$, output $Y(z^{-1})$, and impulse response $H(z^{-1})$ of a discrete LTI system are related as follows:

$$Y(z^{-1}) = H(z^{-1}).X(z^{-1}) \quad (5)$$

where the z -transform of time series $f(t)$ with sampling interval T is given by

$$F(z^{-1}) = \sum_{n=-\infty}^{\infty} f(nT)z^{-n} \quad (6)$$

Inspection of the complex roots of the z -transform polynomials in Eq. (5) in the Argand plane can provide important information regarding the system impulse response. De Laine (1970), for example, suggested that the unit hydrograph for a catchment rainfall-runoff model could be estimated via comparison of the roots of the runoff polynomials corresponding to different storm events. Runoff roots having similar locations in the Argand plane were assumed to correspond to the catchment system and not the input. Turner et al. (1989) similarly suggested that roots for a single runoff time series that fell along a “skew circle” in the Argand plane could be attributed to the unit hydrograph and thus allow for its identification. In seismic data analysis, examination of the roots of $H(z^{-1})$ also has important implications for the stability of inverse filtering operations such as deconvolution; if the roots of the wavelet polynomial under consideration lie outside the unit circle $|z| = 1$, the deconvolution operation will be unstable. Further, if one considers of the LTI system as a rational function in the z -transform domain, i.e.,

$$H(z^{-1}) = \frac{A(z^{-1})}{B(z^{-1})} \quad (7)$$

where $A(z^{-1})$ and $B(z^{-1})$ correspond to moving-average and feedback operations, respectively; the positions of the roots of $A(z^{-1})$ (zeros) and those of $B(z^{-1})$ (poles) in the complex plane with respect to the unit circle can be used to understand the system frequency response as well as design effective digital filters for environmental data.

Summary

The Argand diagram provides a means of plotting a complex number in the form of $z = x + iy$, using the ordered pair (x, y) as coordinates and where the constant i represents the imaginary unit, i.e., $\sqrt{-1}$. The Argand diagram (or plane) is

therefore defined by two orthogonal axes, a real one (abscissa) and an imaginary one (ordinate). In many areas of the geosciences, complex numbers play an important role, and the Argand diagram can serve as a useful tool for data analysis. Examples are provided regarding dispersive material properties, linear time-invariant (LTI) system identification, and digital filter design, as well as seismic data analysis.

Artificial Intelligence in the Earth Sciences

Norman MacLeod
Department of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, China

Definition

There are many definitions of artificial intelligence (AI), but perhaps it is most commonly understood to mean any machine, computer, or software system that accepts information and performs the cognitive functions humans associate with intelligence, such as learning and problem-solving. Part of the difficulty in defining AI more precisely is that no common, universally accepted, formal definitions of the core concepts needed to define human intelligence exist (e.g., thinking, intelligence, experience, consciousness).

Regardless, this difficulty has not prevented philosophers, artists, writers, filmmakers, scientists, engineers, and/or earth scientists from imagining what an artificially intelligent device might be like, how it might be constructed, what it might be used to do, and what dangers it might pose.

Introduction

Few can have failed to notice the plethora of news bulletins, editorials, perspectives, symposia, conferences, course offerings, lectures, and the like that, over the past few years, have announced the imminent arrival of artificially intelligent machines. These are portrayed as being designed to assist with the tasks traditionally assigned to human workers in fields that, thus far, have proven resistant to automation. While not muted (so far) as a replacement for scientists, artists, or senior managers, presumably because of the creativity required by these fields, there is widespread agreement among employers that many repetitive tasks could, and perhaps should, be given over to automation if possible. In addition to creativity, scientific research often involves complex, laborious, and time-consuming searches through datasets, library references, catalogues, image sets, and, increasingly, online resources for bits of information critical to the resolution of a particular problem at hand or hypothesis test. In principle, many researchers would welcome access to automated intelligent agents that could conduct such searches quickly, systematically, and objectively, thus freeing themselves, their colleagues, their assistants, and their students to focus on tasks better suited to their training, knowledge, and core interests. The Massachusetts Institute of Technology's recent announcement that a team of its medical researchers used a deep-learning system named "Hal" successfully to find new generalized antibiotic molecules that kill a number of the most common disease-causing bacteria after screening more than 107,000,000 candidate molecules represents an interesting case in point, especially insofar as the material discovered often exhibited a form structurally divergent from conventional antibiotics (Stokes et al. 2020). Consequently, current debates over artificial intelligence (AI) techniques and technologies are as relevant – though perhaps not quite as threatening – to research scientists as they are to professionals in other areas of human activity.

Curiously, the earth science community appears to be of two minds regarding AI. On one hand, the use of computer software designed to process and identify patterns in earth science data without having to be programmed explicitly to do so is old hat in many fields, so ubiquitous it hardly bears comment. On the other hand, some recent articles have claimed earth science research is either unusually susceptible to the misuse of AI (e.g., Ebert-Uphoff et al. 2019) or focuses on problem classes inherently resistant to AI-based

approaches (e.g., Anonymous 2019; see also Reichstein et al. 2019). Instead, these critics advocate a vaguely defined partnership between traditional “physical process models” and artificial expert systems. At present, the focus of most new AI applications in the earth sciences has centered on machine learning systems and software, especially the newer “deep-learning” artificial neural network architectures. However, machine learning is only one aspect of the much larger artificial intelligence field. In order to determine whether AI has a past, present, or future in earth science research, a more general review is required.

What Is Artificial Intelligence?

The earliest written record of an AI device was the character of ΤΑΛΩΝ or Talon (also Talos) which was a giant robot made of bronze, gifted to Europa by Zeus, that circled the island triannually and threw stones at approaching ships to protect the island from invaders. Modern variations of the Talon myth can be found in Homer’s description of Hephaestus’ serving devices in the *Iliad*, the Jewish parable of the Prague golem, Mary Shelly’s *Frankenstein*, Arthur C. Clark’s HAL from 2001: *A Space Odyssey*, Ridley Scott’s dystopian epic *Blade Runner* (based on the Philip K. Dick novel *Do Androids Dream of Electric Sheep?*), and latter installments of the *Terminator* film franchise.

The first computational steps toward realizing artificial intelligence were taken by Alan Turing, the mathematician and computer-design pioneer who understood that binary arithmetic could be used to perform any conceivable act of mathematic deduction. This insight led to the Church-Turing thesis (Church 1936; Turing 1937, 1950) which was a key advance that ultimately enabled digital computers to be designed. At the same time, several researchers recognized the similarity between Turing’s switch-based computational system and the operation of mammalian neurons which are the fundamental units of the human nervous system. This transfer of insight across disciplines led to Warren McCulloch and Walter Pitt’s (1943) proposal of a design for a Turing-complete artificial neuron and the possibility of constructing a complete, artificial, electronic brain. In the wake of these mid-twentieth-century developments, the MIT and Stanford University computer scientist John McCarthy coined the term “artificial intelligence” to describe machines that can perform tasks characteristic of human intelligence such as planning, understanding language, recognizing objects and sounds, learning, and problem-solving (McCorduck 1979). McCartney’s list of the tasks or capabilities that define AI operations is still reflected in the major components of this field (Fig. 1).

Development and Activity Domains

Two broad classes of AI are recognized: narrow AI and general AI. Narrow AI includes all devices and systems that have some characteristics of human intelligence. Systems that exhibit narrow AI have existed at least since the late 1950s (e.g., Samuel 1959), and it is devices of this sort that are being referred to in contemporary media reports of specific, realized AI applications. The list of fields in which narrow AI systems have, or could be, applied is very long indeed.

No general AI system currently exists, in part owing to lack of agreement of the characteristics such a system would need to possess in order to be so designated, but also owing to the broad assumption that genuine general AI system would need to be self-aware or exhibit consciousness. The basis of fear over the capabilities of a general AI system can be traced to the assumption that a conscious system would seek to establish local or general dominance in the sense many social biological species do. But as Pinker has noted, dominance is usually associated with mammalian male behavior patterns and is derived from genetic strategies that have no necessary correspondence to AI system development goals (<https://bigthink.com/videos/steven-pinker-on-artificial-intelligence-apocalypse?jwsourc=cl>). Conscious AI systems could, just as easily, adopt a female perspective and prioritize problem-solving along with social coherence.

Six activity domains are commonly recognized by AI researchers. These are identified principally by the problems associated with each rather than by the technologies or algorithms that happen to be associated with attempts to address these problems at any given time. Activity has waxed and waned within and between each of these domains over the course of the past 75 years as new approaches were tried and met either with success or failure. Indeed, the methods employed in the current most active domain – machine learning – are being applied, in whole or in part, to all of the other domains at present. Since this domain is the subject of a separate article in this volume, only a very abbreviated description of its core concepts and scope will be provided here. However, it is important to note that the inherent topical disparity that exists within this field has, at certain times, been as much a hindrance as a help to its overall development.

In her history of AI, Pamela McCorduck (1979) noted that, soon after its formulation, AI shattered into subfields, the practitioners of which “would hardly have anything to say to each other” (p. 424). This self-inflicted breach of cohesion and collegiality, along with a tendency to overpromise and under-deliver to funders, exposed AI research to criticisms that led to a reduction in both academic interest and extra-academic support funding over two successive intervals. The first of these “AI winters” extended from 1974 to 1980 and was precipitated by the very damaging US Automatic Language Processing Advisory Committee (ALPAC) report into

Artificial Intelligence in the Earth Sciences, Fig. 1 Schematic representation of the primary domains of contemporary artificial intelligence research and applications. A non-exhaustive listing of some

subordinate activity domains has been provided as a rough indication of domain diversity as well as relative activity levels

prospects for machine translation (Pierce et al. 1966) and the report of Sir James Lighthill (1973) into the state of AI research in the UK. The second AI winter, from 1987 to 1995, was caused by the collapse of the commercial market for AI-based, specialist expert system computers, especially those based on the LISP processor (LISP machines) that employed a syntax close to that of natural language to manipulate source code as if it were a data structure. Arguably, these difficulties for the whole of the AI field were not addressed successfully until the advent of convolution-based artificial neural networks in the late 1990s (e.g., LeCun et al. 1998). It is from this point that the present revival of AI's fortunes has stemmed.

Expert Systems

Expert systems are computer systems that accept information, usually in the form of alpha-numeric data, and employ various processing strategies to address problems via autonomous reasoning based on relations known, or suspected, to exist in a set of data rather than by passing the data through a set of deterministic mathematical procedures. Expert systems were among the first successful AI applications, proliferating commercially in the late 1970s through 1980s via sales of dedicated computer systems based on the LISP family of computer languages, all of which are based on Alonso Church's (1936) development of lambda calculus. Interestingly, LISP is the second oldest computer language, the first versions of which were released in 1958, just 1 year after the release of the first FORTRAN compilers (Wexelblat 1981).

Typically expert systems are organized into a knowledge base and an inference engine. The knowledge base contains definitions, facts, rules, and systems of weights that govern how the rules are applied in particular situations. These rules can be provided by human experts based on their personal or collective knowledge or transferred from the inference engine based on the system's experience processing datasets. In this way, the knowledge base can grow and improve the system's performance giving the system, overall, a degree of machine learning capability. The inference engine applies the knowledge base to data and, by virtue of relations identified within and between datasets, can infer new facts/rules that, in turn, can be passed back to the knowledge base. Classic expert system designs represent knowledge, for the most part, via specification of if-then rules. In this sense, expert system designs resemble aspects of decision trees.

Many information-technology historians date the introduction of expert systems to 1965 and the Stanford Heuristic Programming Project whose original application was to identify novel organic molecules based on their mass spectra with a rule set derived from human expert knowledge of organic chemistry. In 1982, the Synthesis of Integral Design (SID) system was the first system to generate a set of logical routines sufficiently extensive to outperform expert logicians. Despite

these milestones, however, the performance predictions made by advocates of expert systems failed to be realized and were recognized to have fallen short of expectations by the late 1980s. The reasons behind the inherent limitations in expert system designs had been studied and explained by Karp (1972). But in the early optimism over AI his concerns were discounted or ignored. Nevertheless, failure to meet expectations and deliver on commercial investments in expert systems caused a collapse of the market for specialist systems by the late 1980s, a situation from which classical LISP-based expert systems never really recovered, though aspects of expert system design continue as codified algorithms in many business-analysis applications. Hayes-Roth et al. (1983) published an extensive summary and classification of expert system designs which remains a standard reference.

Natural Language Processing

The very large field of natural language processing (NLP) includes all aspects of the theory and application of the ability of humans and computers to interact with one another using natural spoken or written languages. While machines that speak and understand what is being said when spoken to have been a staple of science fiction for over a century, sophisticated and effective NLP applications are familiar to most people today in the form of personal computer assistants such as Apple Corporation's *Siri*, Google's *Google Assistant*, and Amazon's *Alexa*, in addition to a plethora of online automated technical service and customer support systems that respond to typed text. This field represents the intersection between linguistics, computer science, information engineering, and AI.

Alan Turing (1950) regarded NLP as a primary goal of AI in the form of his "imitation game" – later referred to as the "Turing test" – for the degree to which any machine can be judged to demonstrate intelligent behavior. Turing's test has been criticized for confusing the concepts of thinking and acting, but it remains a well-known, popular, and (so) important AI benchmark. This concept probably inspired, at least in part, the so-called Georgetown experiment a few years after Turing's article appeared when, in 1954, an IBM 701 mainframe computer successfully translated 60 Russian sentences into English based on a dictionary of 250 words and a knowledge base of six rules (Hutchins 2004). Not only did this demonstration receive wide media coverage, it stimulated government and commercial interest in NLP, and in AI generally, prompting some to predict generalized systems for language translation could be produced by 1960. When this goal had not been achieved by the mid-1960s, it prompted a withdrawal of US government funding, precipitating the first AI winter.

Natural language processing systems were based originally on expert-determined rule sets. This design was replaced in the late 1980s by a statistical approach in which

Artificial Intelligence in the Earth Sciences, Fig. 2 Example of a typical hidden Markov model. In this situation, the task is to infer the state of the weather by collecting data on what a friend who lives in another city is doing. Since you cannot observe the weather there, that layer is hidden. But if probabilities can be assigned to various weather-

dependent activities, its state can be inferred by collecting information about the friend's activity. If the friend spent the day shopping, there's a 40% chance it was raining. But if they went for a walk, there's a 60% chance it was sunny. (Redrawn from an original by Terrance Honles: see <https://commons.wikimedia.org/wiki/File:HMMGraph.svg>)

rules were learned by systems analyzing large sets of documents and could be applied in a probabilistic manner that incorporated information from context. Modern NPL systems are quite sophisticated and are gaining in accuracy, and popularity, with each passing year. Amazon's *Alexa* is representative of the best of the current crop of NPL devices. *Alexa* records ambient sounds (= listens) continuously and subdivides spoken words into individual phonemes. When the "wake" word "Alexa" is detected, the statement that follows is shunted to a very large database of word pronunciations to find which words most closely correspond to the combinations of sounds. A second (huge) database of likely phrases is then searched to infer the most likely word order using a hidden Markov model (Fig. 2; also see Rabiner 1989). Once the statement has been reconstructed, the *Alexa* system searches the statement for important or key terms that signal instructions to perform particular tasks. All these searches, inferences, and reconstructions are performed in real time using cloud computing. Responses to spoken commands are formulated in the same manner, but in reverse order.

Owing to the combination of deep learning with NLP, along with the number of times they are used by system subscribers, the performance of these systems is improving rapidly. Moreover, the recent release of 5G network technology will enable NPL systems such as *Siri*, *Google Assistant*, *Alexa*, and others to communicate with an ever-increasing array of devices so they can, effectively, serve as intermediaries for two-way human-device communication. This

capability is set to have an extremely wide range of applications, including scientific research.

Machine Learning

Without question, machine learning (ML) is the AI activity domain that has received the most attention over the last two decades, driven largely by a revival of interest in artificial neural networks (Only the basics of machine learning will be covered in this section. The reader is directed to the companion article in this volume for additional information.). Formally ML is the study and application of algorithms that enable computer systems to learn and improve performance in specific task areas without being programmed explicitly to do so. This is an algorithmically diverse and mathematically complex field that, to this author's way of thinking, has its conceptual origins in multivariate data analysis, especially eigenvector-based methods such as principal component analysis (ordination, dimensionality reduction) and multi-group discriminant analysis (classification). The techniques and search strategies employed by current machine learning systems are far removed from these origins, and, given adequate data, their performance exceeds those delivered by these original and more primitive approaches by a very substantial margin. But on a conceptual level the goals are largely the same.

Key to understanding the core structure of ML is the difference between unsupervised and supervised learning. Both approaches require a set of representative data used to

train algorithms to identify regularities and differences among subgroups contained therein. Like all statistical samples, these training data must (ideally) constitute an unbiased, representative summary of patterns present in the parent population of interest, at least at the level of resolution necessary to address the problem at hand. In most cases, owing to the complexity of the machine learning algorithms and the number of variables that must be estimated, the size of the training dataset must be large; uncommonly large in many instances though this depends on the distinctiveness of the subgroups included in the population of interest, or lack thereof.

In any unsupervised learning problem, only the training dataset is input and the task is twofold: (1) determination how many different groups of observations are present in the training data and (2) identification of characteristic patterns of variation within and between these subgroups that will allow unknown observations to be associated with the correct subgroup. Under a supervised learning design, the classification, or pattern of group membership, present in the training data is known before training is undertaken; this information is supplied to the system at the outset of training, and only the second learning task is performed. Under both approaches, assessments of training performance and/or evaluations of the training dataset are made post hoc, preferably via reference to a new or validation dataset whose members were not part of the training process (If necessary, it is permissible to approach the estimation of post-training performance using a jack-knifed testing strategy though this cannot be considered as rigorous a test and might be impractical owing to the time required to train ML systems such a large number of times in succession.). Some ML systems employ other learning designs (e.g., semi-supervised learning, reinforcement learning, self-learning, feature learning, transfer learning), but most adopt either a supervised or unsupervised approach with the former being more common at present. A very large and diverse array of algorithm families are currently being employed in ML systems (e.g., logistic regression, Bayesian networks, artificial neural networks, decision trees, self-organizing maps, deep-learning networks). Each has advantages and disadvantages in particular situations, a discussion of which is beyond the scope of this article.

Computer Vision

This activity domain involves more than locating and identifying images, or parts thereof, tasks that properly fall into the domain of machine learning. Rather, computer vision involves imbuing machines with the capacity to understand image-based information and the ability to make decisions or take actions based on that understanding. Specific skills associated with this domain include scene reconstruction, event detection, tracking, object recognition, pose estimation, motion estimation, indexing, and image restoration along with AI.

Since humans have particularly well-developed visual systems, this has been one of the more attractive of the AI activity domains. Interest in computer vision grew out of research into image processing and was funded originally by national militaries interested in the problem of automatically detecting and identifying hostile aircraft. From a strictly AI perspective, however, this field was considered a developmental priority because of its strong link to the issue endowing intelligent devices with ability to move about in local environments autonomously. While vision is but one of the five human senses, the problems associated with its artificial manifestation are, essentially, the same for all the other senses (e.g., signal extraction, boundary recognition, identification, cognition). Therefore, research into the development of computer (or machine) vision has direct implications for the development of other machine senses.

Drawing from its origin in image processing, research into computer vision began in the 1960s with algorithms designed to locate the boundaries and establish the forms of objects in two-dimensional (2D) scenes, but quickly progressed to the inference of three-dimensional (3D) structure from clues provided by shading, texture, and focus. Rapid reconstruction of 3D scenes was aided greatly via the importation of techniques drawn from mathematical bundle adjustment theory (Triggs et al. 1999; Hartley and Zisserman 2004), photogrammetry (Wiora 2001; Jarve and Liba 2010), and graph cut optimization (Boykov et al. 2001; Boykov and Kolmogorov 2003). More recently, this domain has taken a substantial leap forward as a result of developments in image-based, deep-learning subsystems and their incorporation into computer/machine vision systems.

Contemporary, state-of-the-art, computer vision systems have found wide, and increasingly diverse, application in manufacturing system-control and quality-assurance, object identification, surveillance and law enforcement, autonomous vehicle/robot, and military applications. Indeed, these systems have reached the point where, in some respects, their performance is vastly superior to that of (even) expert capabilities (e.g., the sorting of object images into large numbers of fine-grained categories; see Culverhouse et al. 2013), whereas in others they still struggle with tasks humans find trivial (e.g., recognition of small of thin objects).

Planning Systems

Many human activities consist of sequences of actions that, ideally, are directed toward the attainment of a particular goal and, operationally, must be performed in a particular sequence. When the goal is specific (e.g., arrival at a particular destination from a given starting point), the domain over which the plan must be executed limited (e.g., must utilize local road systems or in urban areas, sidewalks, tram lines, or underground railways), and the optimality criterion known (e.g., shortest route, quickest travel time), planning can be a

Artificial Intelligence in the Earth Sciences, Fig. 3

A simple Markov decision process with three states (red), two actions (green), and two rewards (blue). Note the greater dependency of state S_2 on states S_0 and S_1 . (Redrawn from an original by Waldo Alvarez: see https://commons.wikimedia.org/wiki/File:Markov_Decision_Process.svg)

relatively simple exercise. However, when this problem is extended over multiple domains (e.g., multiple destinations, opening/closing times of various attractions along the way) whose characteristics might not be well established and whose states are subject to conditions that may change while the plan is being executed (e.g., traffic), determination of the optimal set and sequence of actions can be very complex. When the set of domains over which the plan must be executed is unknown, the challenge of determining optimal solutions unaided can be daunting. This problem category represents the activity domain of AI-empowered planning systems.

A number of generalized strategies have been developed to address planning problems which are fundamental to a (growing) range of different industries (e.g., logistics, workflow management, career progression, robot task management). For example, the range of possible actions and their consequences can be modeled by a network or as a surface and the optimal path found deterministically via constrained optimization (Bertsekas 2014; Verfaillie et al. 1996), Markovian decision processes (Burnetas and Katehakis 1997; Feinberg and Shwartz 2002, Fig. 3), or trial and error simulations (Kirkpatrick et al. 1983) with alternative routes found, by any of these approaches, as and when information pertinent to the plan's execution and derived from local or remote sensors changes. Alternatively route domains characterized by features that may not be fully observable can be planned using a partially observable Markovian decision process (POMDP) approach (Kaelbling et al. 1998). These procedures can be embedded in a number of different planning

scenarios (e.g., classical planning, probabilistic planning, conditional planning, conformant planning).

Robotics

Owing to the unique problems associated with the construction of machines that can move about in the environment and manipulate objects autonomously, robotics is the AI activity area that has seen the strongest mechanical engineering input. This activity area represents the intersection of electronic engineering, bioengineering, computer science, nanotechnology, and AI.

The first widely acknowledged autonomous robot was developed by George Devol, based on a patent application filed in 1954 (approved in 1961) for a single arm, stationary robot. This industrial robot, the *Unimate*, relied on a unique rotating drum memory module to perform a number of routine tasks. First employed to take die cast auto parts from a conveyor belt and weld them to auto bodies at General Motors' Inland Fisher Guide Assembly Plant in New Jersey, the original *Unimate*, along with the more flexible Programmable Universal Manipulation Arm (PUMA) system, could perform many other tasks.

Today, robots are so common in such a wide variety of manufacturing, construction, agricultural, law enforcement, consumer service, entertainment, emergency/rescue service, medical, and military industries, employ such a wide variety of technologies, and exhibit such an extreme range of designs; the idea of listing their commonalities might seem hopeless. However, all extant robots do share certain features with the

original *Unimate*: (1) mechanical construction, (2) electrical components to power the mechanical parts, and (3) computer programs to control the robot's movements and/or responses to its environment. Not all robots employ AI. Indeed, many simply perform sets of preprogrammed movements activated by remote human control. These devices are better thought of as automations rather than robots per se. However, AI-enabled robots are becoming more common with each passing year and are increasingly able to respond autonomously to changes in local conditions as those are transmitted to the system from various sensors located both on the robot's body and remotely via wireless communication links.

Fully autonomous, mobile, multipurpose, self-actuated robots remain a science-fiction fantasy at the moment. But a veritable international army of well-funded technologists are working diligently toward the ultimate goal of assembling such a device. Already there is growing concern among a variety of philosophical, civil rights, legal, regulatory, public health, law enforcement, and military bodies with regard to the opportunities and concerns the existence of this category of machines will embody. Such concerns are even beginning to be raised within the earth sciences (e.g., Wynsberghe and Donhauser 2018). These concerns are, to some extent, characteristic signs of contemporary interest in the entire subject of AI. Regardless, it is difficult to deny the symbolic role increasingly common, and increasingly autonomous, robots will have in shaping this public debate, irrespective of the many uses, services, capabilities, and economic savings they will provide.

Applications in the Earth Sciences

All forms of AI are currently being employed across the broad range of earth scientist research projects, and earth science researchers have an excellent historical record of taking advantage of the latest developments in this field. Among the first applications of AI technology in a geological context were the PROSPECTOR (Hart and Duda 1977; Hart et al. 1978) and muPETROL expert systems (Miller 1986, 1987, 1993). Both were Bayesian LISP-based systems programmed originally for IBM-PC platforms. PROSPECTOR was a mineral exploration system and was based on the analysis of geochemical data associated with three different types or mineral deposits. It remains available today as PROSPECTOR II (McCammon 1994). The muPETROL system focused on petroleum resource exploration and was based on Klemme's (1975, 1980, 1983) basin classification system with a set of consensus inference rules devised by experienced petroleum exploration geologists. Subsequent geological expert systems include DIPMETER ADVISOR (Carlborn 1982; Smith and Baker 1983), Fossil (Brough and Alexander 1986), EXPLORER (Mulvenna et al. 1991),

ARCHEO-NET (Fruitet et al. 1990), and Expert (Folorunso et al. 2012). Listings and descriptions of additional geological expert systems can be found in Aminzadeh and Simaan (1991) and Bremdal (1998). Expert systems are also available for a number of other earth science disciplines, including oceanography (e.g., Nada and Elawady 2017), atmospheric science (e.g., Peak and Tag 1989), geography (Fisher et al. 1988), and biology (Edwards and Cooley 1993 and references therein).

A number of NLP initiatives have been funded and/or are currently underway in the earth sciences. An initial, albeit limited, attempt to develop a system to automate the extraction of biodiversity data from taxonomic descriptions was developed by Curry and Connor (2007). This system, which included information on the stratigraphic ranges of fossil taxa, was based on the XML markup language which was used to annotate relevant terms, assignments, names, and other taxonomically relevant bits of information in taxonomic descriptions. Once annotated, these data could be migrated quickly, easily, and reliably into relational databases where appropriate data extractions, integrations, and analyses could take place. While the system proposed by Curry and Connor (2007) fell well short of a fully automated NPL system, it did demonstrate the importance of expert-level data annotation. Annotated data of precisely this sort today serve as training datasets for fully automated NPL systems, allowing them to learn how to identify different aspects of text passages to extract and tag for database migration. A more complete and up-to-date discussion of NPL techniques applied to the systematics and taxonomy literature has been provided by Thessen et al. (2012).

A sophisticated and successful fully NPL initiative of this type was the PaleoDeepDive project (Peters et al. 2014), which focused on the extraction of fossil occurrence data from the English, German, and Chinese language paleontological literature. This system employed NPL tools developed for other purposes (e.g., Tesseract and Cuneiform for text, Abbyy Fine Reader for tables, StanfordCoreNLP for linguistic context) to define factor graphs that were then used to aggregate variables (names, stratigraphic ranges, geographic occurrences) into meaningful combinations. The dataset used to train the PaleoDeepDive system was the Paleobiology Database (<http://paleobiodb.org>) which, at the time of training, consisted of over 300,000 taxonomic names and 1.2 million taxonomic occurrences, the majority of which had been extracted by hand from over 40,000 publications. This system was successful in extracting 59,996 taxonomic occurrences from a collection of literature sources that had not been entered into the Paleobiology Database previously.

In another, unrelated, initiative, ClearEarth (<https://github.com/ClearEarthProject>) is a US National Science Fund project established to bring computational linguistics and earth science researchers together to experiment with ways to

extract and integrate data from a variety of sources for the purpose of supporting research within and across the disciplinary fields of geology, ecology, and cryology. ClearEarth employs the ClearTK package of NPL routines, which is a well-established system for processing medical patient notes that is used on a routine basis by a large number of institutional health providers (Thessen et al. 2018). In essence, ClearEarth represents an attempt to port a mature and proven NPL technological infrastructure to aspects of earth science where, it is hoped, a similar penetration of institution-level integration and usage will result. Since 2016, ClearEarth has focused on the expert-informed markup of a well-annotated corpus of earth science text sources that will be used to train the ClearEarth system. To date, this project has released annotation guidelines for sea ice and earthquake events as well sponsoring a “hackathon” in 2017 at the University of Colorado (Boulder) where bio-ontologies were produced and extended.

Additional NPL earth science research and management areas that have undertaken NLP-based initiatives include oceanography (e.g., Manzella et al. 2017) and geography (e.g., Lampoltshammer and Heistracher 2012 and references therein).

Machine learning applications in the earth sciences are very common and have received a substantial boost over the past decade with the arrival of high-performance convolution neural network and deep-learning architectures. Examples will be reviewed in the companion to this article. For the sake of completeness though, a few references to reviews and initial trials of ML applications in various earth science fields are provided for the fields of stratigraphy (Zhou et al. 2019), sedimentology (Demyanov et al. 2019),

paleontology (Monson et al. 2018), mineralogy (Caté et al. 2017), petrology (Rubo et al. 2019), geophysics (Russell 2019), archaeology (Nash and Prewitt 2016; MacLeod 2018), geography (Kanevski et al. 2009), systematics and taxonomy (MacLeod 2007), biology (Tarca et al. 2007), ecology (Christin et al. 2019), oceanography (Dutkiewicz et al. 2015), glaciology (Zhang et al. 2019), atmospheric sciences (Ghada et al. 2019), and climate sciences (Cho 2018; Reichstein et al. 2019).

In the area of robotics, many of the most exciting AI developments have come from an earth science context. Two interesting recent deployments in this area are the EU-funded UNEXMIN project’s *UX-1* underwater mine exploration robot and the Woods Hole Oceanographic Institution’s (WHOI) *Nereid Under Ice* robot (Fig. 4).

The UX1-Neo was developed by the European Union’s UNEXMin project primarily as an autonomous system for mapping and assessing Europe’s flooded mines into which it would be extraordinarily dangerous for humans to venture, much less work. Various *UX-1* systems currently exist each with a different set of sensors and analytic packages onboard. The system is designed to operate completely autonomously with only a guideline attached so the robot can be recovered if it becomes stuck or ceases to function properly. Aside from the technological challenge, creation of the UX1 series was justified as a means of determining whether it would be feasible and commercially profitable to reopen old, disused, flooded properties to extract rare-earth elements whose price has escalated dramatically in recent years. Regardless, such a system would be useful in many other earth science contexts.

In a similar vein, the WHOI *Nereid Under Ice* robot was recently sent to explore the Kolumbo volcano off Greece’s Santorini Island. Santorini was, of course, the site of one of

UX1-Neo

Nereid Under Ice

Artificial Intelligence in the Earth Sciences, Fig. 4 Portraits of the UNEXUP UX1-Neo robot with autonomous capabilities and the WHOI *Nereid* under the ice robot which was rendered fully autonomous via installation of an automation technology package developed by NASAs

PSTAR program. Autonomous robots such as these are pioneering AI technology developments that will have broad application across the earth and space sciences in the coming years. Image credits UNEXMIN and NOAA for the UX1-Neo and *Nereid* Under Ice robots respectively

the largest volcanic eruptions recorded in human history. For the 500 m Santorini dive, the *Nereid* was equipped with a new automation-technology package developed by US National Aeronautics and Space Administration's (NASA) Planetary Science and Technology from Analog Research (PSTAR) program. This NASA-PSTAR package included an AI-driven planning system that allowed the *Nereid* to plan its own dive as well as to determine which samples to take and how to take them. On the Santorini dive, the AI-enabled *Nereid* became the first robot to collect an underwater sample autonomously (see video clip at: <https://www.whoi.edu/press-room/news-release/whoi-underwater-robot-takes-first-known-automated-sample-from-ocean/>).

Both the UX1-Neo and NASA-PSTAR system-equipped *Nereid* represent a new breed of fully autonomous robots that will not only fill critical gaps in the capabilities of earth scientists now, but also provide test beds for the development of new and even more sophisticated autonomous robots in the future, for use both here on Earth and beyond.

While many believe the most efficient way to explore the geologies of distant planets is via a remote controlled robot (e.g., Spudis and Taylor 1992), and despite the fact that all current lunar and Martian rovers have been remotely controlled automations, the distances involved in the exploration of Mars and the moons of Jupiter and Saturn are such that a large degree of autonomous capability will need to be incorporated into the designs of future planet-exploration robots (Anonymous 2018). At present the ExoMars Phase 2 Mission (due to be launched in 2022) will include a substantially automated robotic system designed to complement the ExoMars Phase 1 Mission (launched in 2016). The difference between the levels of autonomous capability incorporated into these two rovers reflects developments – and confidence – in the field of robot autonomous systems (RAS) over the past

5 years. Similar levels of autonomous robotic capabilities are expected to be part of the Mars Sample Return (MSR) Mission (expected launch 2026), Martian Moon (Phobos) Sample Return Mission (expected launch 2024), and various orbital missions currently in planning stages.

Planning Systems

While AI planning systems might appear to have more to do with the logistics of earth science research than the science itself, it is possible to take a broader view of planning which is, in essence, an attempt to order a set of data into a sequence according to some error-minimization criterion. In this context, the routine – though complex – task of inferring the correct sequence of stratigraphic datums from samples collected from multiple stratigraphic sections or cores is not dissimilar to a planning problem. Here, the geologist/stratigrapher must infer the correct order a set of stratigraphic datums whose true order is obscured by a variety of distributional and preservation factors (Fig. 5). This problem can be approached in many ways (e.g., Shaw 1964; Gordon and Reymont 1979; Edwards 1989; MacLeod and Keller 1991). However, several recent and quite sophisticated approaches have treated it as a quasi-planning problem and developed either probabilistic (Agterberg et al. 2013), rule-based (Guex and Davaud 1984; Guex 2011), or constrained optimization (Kemple et al. 1995; Sadler and Cooper 2003; Sadler 2004; Fan et al. 2020) approaches to its solution; approaches that, in the case of the latter, strongly mimic that of an AI-based planning system approach.

Artificial Intelligence in the Earth Sciences, Fig. 5 Stratigraphic coexistence matrix before (left) and after (right) permutation to infer the correct relative order, or slotting, of the datums. In a spatial sense, this problem is similar to a minimum trip distance problem in which the distances between locations are known, but the most efficient sequence

of destinations is not. Such problems can be solved using an AI-based planning system approach. For these data, the coexistence of B and G is implied but not observed. The column of numbers to the right represent reciprocal averaging scores. (Redrawn from Sadler 2004)

Conclusion and Prospectus

Artificial intelligence-based applications have been a part of earth science research and industrial applications for over 40 years, virtually as long as such applications have been available for use outside the fields of mathematics and information technology. Levels of interest and activity in AI by the earth science community have waxed and waned over these decades in much the same way as the fortunes of AI generally. While it is true most of the activity in this community has come from technology and data-analysis enthusiasts, AI is undergoing a renaissance of interest across the earth science disciplines currently, which mirrors renewed government and commercial interest in AI-based solutions to a wide range of technical, technological, and social problems generally. In large part, this renewed interest has been driven by advances in the machine learning AI activity domain. But these advances have had the effect of stimulating research, development, and interest in all forms of AI.

Many seem to be concerned with the effect AI will have on the direction of the fields to which it is applied and especially on the employment prospects for young people. Such concerns are, in my view, misplaced. Earth sciences as a whole have become increasingly quantitative over the past 70 years, and there is little evidence to support a conclusion that this has led to unethical practices, or reduced employment prospects, in the sector. Routine identification, sampling, and data-collection tasks are, increasingly, able to be performed by quasi-autonomous AI-enabled machines. This trend is very likely to continue. But in many ways it is these tasks that often take us away from the more creative and integrative aspects of our science; two areas of performance AI approaches struggle to deliver. In addition, it is simply beyond question that human experts suffer from a wide variety of performance limitations that the use of AI-based technologies can assist in addressing (e.g., MacLeod et al. 2010; Culverhouse et al. 2013). Instead of viewing the rise of AI as a threat to the development of the earth sciences, the community should, as it has with other technological advances in the past, welcome such developments as much-needed and much-valued facilitators/partners in the task of exploring and understanding our planet and its inhabitants: past, present, and future.

As with any genuine partnership though, both sides need to work to make the most of the collaboration. Devices that employ aspects of AI can be massive boon to earth science research, but AI cannot deliver on this promise alone. In order to be effective, AI systems need data and guidance. Earth scientists have data, but we have not been diligent in aggregating, cleaning, updating, and making our data available. Various earth science big data initiatives are currently

underway (e.g., Spina 2018; Normile 2019; Stephenson et al. 2019). These need not only to be supported and contributed to by earth scientists, but the guidance AI applications need must be delivered via engagement with, and active participation in, AI-related initiatives by expert earth scientists of all types. In addition, the training of students interested in the earth sciences at all levels needs to be reorganized and expanded to equip them with the skills they will need to take full advantage of the coming AI revolution. Finally, the earth science community needs to establish AI as a priority – perhaps a top priority – for ensuring the future success of our science through the diverse, ongoing professional education, outreach, and influencing activities of our professional societies.

Definition

An artificial neural network (ANN), also known as neural network, is a computational model capable of processing information to tackle tasks such as classification and regression. It is the component of artificial intelligence inspired by the human brain and nervous system.

Introduction

Artificial neuron and the coding signals in an ANN are used to simulate the electrical activities of how the nervous system communicates. Each artificial neural neuron receives input signals, processes these signals, and generates an output signal. A general practice is to sum the weighted inputs, and then feed the sum value into a transfer function to judge if the value is qualified to be transferred to another neuron as an input. The simplest transfer function is to compare the sum value with the set threshold, while nonlinear functions allow more flexibility.

Starting from the 1940s, ANNs have evolved from perceptron, an algorithm for supervised learning of binary classifiers, through backpropagation, a way to train a multi-layer network, to deep learning. One of the reasons why ANNs have become so popular is that the network's self-learning capability of ANNs enables them to solve complex

problems, which are difficult or unfulfillable for humans, and even produce better results than statistical methods. Also, they can deal with incomplete, noisy, and ambiguous data.

Nowadays, ANNs are used in a variety of research and industrial areas. The applications of ANNs are wide, encompassing engineering, finance, communication, medical, and so on. The use of ANNs in geography stems from the need to handle big spatial data. With the development of geo-information technologies such as Remote Sensing (RS), Geographic Information System (GIS), and Global Navigation Satellite System (GNSS), spatial data processing and analysis begin to ask for artificial intelligence to handle complex geographical problems.

The purpose of this encyclopedia entry is to introduce the basic concept of ANNs, review major applications in geoinformatics, and discuss future trends.

ANN Models

Components of ANNs

ANN refers to an artificial neuron system built by imitating human neurons for information processing. It is a computing model, which is composed of a large number of interconnected **neurons**. The neuron can be regarded as a calculation and storage unit. A single neuron generally has multiple inputs. After some calculations (i.e., weighted addition), the output will be used as the input of subsequent neurons. In a neural network, every **connection** between two neurons represents a **weight** to reflect the strength of the connection. Finally, neurons are combined layer by layer to form a neural network (Fig. 1).

In more detail, let a_i to represent the inputs of a neuron, and w_i to represent the weights on the connections. Then, the output of this neuron would be

$$z = f(\text{sum}(w_i w a_i)),$$

where f represents an activation function. With the help of the activation function, what a neuron can do is more than just weighting and summing the received information and outputting it to the next neuron. The activation function simulates such a process. In reality, neurons in the organism are not

necessarily activated after receiving information, but determine whether this information has reached a threshold. If the value of the information does not reach this threshold, the neuron is in a state of inhibition, otherwise, the neuron is activated and transmits the information to the next neuron. Similarly, a neuron in an ANN would decide whether and how to pass the information. In order to improve the utilization of neurons, nonlinear functions are usually used instead of thresholds as the activation functions of neurons. Besides, by introducing nonlinear activation functions, a neural network can theoretically fit any objective function, making it powerful.

Organization

Structurally, a neural network can be divided into input layer, output layer, and hidden layer. The input layer accepts signals and data from the outside world, and the output layer realizes the output of the system processing results. The hidden layer is between the input layer and the output layer and cannot be observed from outside the system.

When designing a neural network, the number of neurons in the input layer and output layer is often fixed, and the hidden layer can be freely specified. The number of hidden layers and the number of neurons in each layer determine the complexity of the neural network. In the 1950s, ANN presented itself in the form of a perceptron, without a hidden layer. Later in the 1980s, ANN was developed into a multi-layer perceptron, with only one hidden layer. From 2012, ANN tended to have more and more hidden layers (deep learning). The reason for the development of neural network structure is that as the number of layers increases, the parameters of the entire network increase. More parameters mean that the simulated function by ANN can be more complicated to solve harder problems (Fig. 2).

Learning

A neural network training algorithm is to adjust the value of all the weights to the best, so that the prediction performance of the entire network could be the best.

In order to fit the target better, the neural network needs to know how far the prediction is from predicted target. Let the sample be y_p and the true target be y . Then, loss function needs to be defined to measure the distance between y_p and y , so as to define what weight parameters are appropriate. There are some different loss functions in practice. For example, the calculation formula could be as follows.

$$\text{loss} = (y_n - y)^2$$

Then, the training goal is to minimize the loss function and make the prediction result of the neural network for the input sample closer and closer to the true value by adjusting each

Artificial Neural Network, Fig. 1 (a) a natural neuron vs. (b) a neuron in an ANN

Artificial Neural Network, Fig. 2 The development of neural network structure. (a) perception; (b) multilayer perception, MLP; (c) deep learning

weight parameter. In practice, the optimization algorithm represented by the gradient descent method can be used to solve the above minimization problem. The back-propagation method is the specific implementation method of the gradient descent method on the neural network. Its main purpose is to pass the output error back and distribute the error to all the neurons of each layer, so as to obtain the error of each neuron, and then modify each weight accordingly.

In general, in ANN Models, a collection of artificial neurons are created and connected together, allowing them to send messages to each other. The network is asked to solve a problem, so it attempts to make it by iteration, each time strengthening the connections that lead to success and diminishing those that lead to failure.

Applications

Tasks suited for ANNs are classification, regression and clustering, etc. ANNs have been applied in many disciplines, especially in earth science.

ANNs have a long history of use in the geosciences (Van der Baan and Jutten 2000), such as hydrology, ocean modeling and coastal engineering, and geomorphology, and they remain popular for modeling both regression and/or classification (supervised or unsupervised) of nonlinear systems. As the early landmarks, the revival of neural networks applied on high-resolution satellite data were applied to classify land cover and clouds (Benediktsson et al. 1990; Lee et al. 1990) almost 30 years ago. In addition to spatial prediction, ANNs have also been used to study dynamics in the earth systems by mapping time-varying features to temporally varying target variables in land, ocean, and atmosphere domains. For instance, by using (multitemporal) remote sensing data, ANN can be used to detect forest changes caused by a prolonged drought in the Lake Tahoe Basin in California (Gopal and Woodcock 1996). Also, an artificial neural network with one hidden layer was able to filter out noise, predict the

diurnal and seasonal variation of carbon dioxide (CO₂) fluxes, and extract patterns such as increased respiration in spring during root growth (Papale and Valentini 2003). In these early works, ANNs were proved to provide better classification or regression performance compared to traditional methods in given scenarios. However, compared to statistical-based machine learning (ML) methods, ANNs do not have many overwhelming advantages.

Deep neural networks (DNNs), or deep learning (DL), extend the classical ANN by incorporating multiple hidden layers and enable good model performance without requiring well-chosen features as inputs. DNNs have attracted wide attention in the new millennium, mainly by outperforming alternative machine-learning algorithms in numerous application areas. In 2012, AlexNet, a convolutional neural network (CNN) model won Imagenet's image classification contest with an accuracy of 84% jump over 75% accuracy that earlier ML models had achieved based on its efficient use of graphic processing units (GPU), rectified linear units (ReLUs), and large training data volume. This win triggers a new DNN boom globally.

In the geoscience domain, researchers observe, collect, and process geological data and discover interested knowledge of the geoscientific phenomenon from the data. While the earth system is a complex system, building a quantitative understanding of how the Earth works and evolves by using traditional tools from geology, chronology, physics, chemistry, geography, biology, and mathematics becomes difficult. However, as the volume of data accumulated through long-term tracking and recording, the scientific research paradigm shifts from knowledge-driven to data-driven (Kitchin 2014). This shift provides opportunities for ANN-based machine learning methods in geoscience fields, as they can capture nonlinear relationships between the inputs as well as reduce the dimensions of the model and help convert the input into a more useful output.

Specifically, there are mainly three popular research fields in geomatics:

- Although applications to problems in geosciences are still in their infancy (Reichstein et al. 2019), tasks using remote-sensing images benefit a lot by introducing deep learning methods that are rapidly developing in computer science. Since 2014, the remote sensing community has shifted its attention to DL, and DL algorithms have achieved significant success at many image analysis tasks including land use and land cover classification, scene classification, and object detection. CNN is more popular than other DL models, and spectral-spatial features of images are utilized for analysis. The main focus of the studies is on classification tasks, but several other applications are worth mentioning, including fusion, segmentation, change detection, and registration. Therefore, it appeared that DL could be applied to almost every step of the remote sensing image processing.
- In solid Earth geoscience, DNNs trained on simulation-generated data can learn a model that approximates the output of physical simulations (Bergen et al. 2019). It can be used to accurately reproduce the time-dependent deformation of the Earth (DeVries et al. 2017), or perform fast full wavefield simulations by training synthetic data from a finite difference model using CNN model (Moseley et al. 2018). In another example, Shoji et al. (2018) use the class probabilities returned by CNN to identify the mixing ratio for ash particles with complex shapes. Several recent studies have applied DNNs with various architectures for automatic earthquake and seismic event detection, phase-picking, and classification of volcano-seismic events. All these tasks are difficult for expert analysts.
- In dynamic earth system researches, such as climatology and hydrology, ANNs, especially DNNs, also play a vital role. For instance, a neural network was used to predict the evolution of the El Niño Southern Oscillation (ENSO) and it shows that ENSO precursors exist within the South Pacific and Indian Oceans (Ham et al. 2019). Recent studies demonstrate the application of deep learning to the problem of extreme weather, for instance, hurricane detection (Racah et al. 2017). Also, Gagne II et al. (2019) employed neural networks to predict the likelihood that a convective storm would produce hail, showing that the neural networks made accurate predictions by identifying known types of storm structures. The studies report success in applying deep learning architectures to objectively extract spatial features to define and classify extreme situations (for example, storms, hails, atmospheric rivers) in numerical weather prediction model output. Such an approach enables rapid detection of such events and

forecast simulations without using either subjective human annotation or methods that rely on predefined arbitrary thresholds for wind speed or other variables.

Conclusions

Based on many existing works in recent years, the adoption of ANNs in geoinformatics are quite successful. Although ANNs have been widely used in geoscience applications, geoscientists sometimes hesitate to use them due to the lack of interpretability. The ANN is criticized as being oversold as a “black-box” with output oriented regardless of understanding the network structure.

Recently, there have been efforts within the geoscience community to compile methods for improving machine learning model interpretability (Gagne II et al. 2019; McGovern et al. 2019). These interpretation methods are applied to trace the decision of a neural network back onto the original dimensions of the inputs and thereby permit the understanding of which input variables are most important for the neural network’s decisions. Backward optimization and layerwise relevance propagation (LRP) reveal that the neural network mainly focuses its attention on the tropical Pacific, which is consistent with expert perception (Toms et al. 2020). This can help uncover the “black-box” construction of ANNs. Also, expert knowledge can be introduced to educate the network structure formation and optimization. Empirical, inner model comparisons and assessments are needed to facilitate understanding of the physical mechanism of the spatial processes. Therefore, for geoscientists who embrace neural network methods, interpretable ANNs will be one of the promising directions where breakthroughs may be made.

Autocorrelation

Alejandro C. Frery

School of Mathematics and Statistics, Victoria University of Wellington, Wellington, New Zealand

Synonyms

Second moment; Serial correlation (when referring to time series)

Definition

The autocorrelation is a measure of the association between two random variables of the same process. In geosciences; it is often called autocovariance.

There are many ways of measuring the association of two random variables. Among them, the Pearson coefficient of correlation between two random variables $X, Y: \Omega \rightarrow \mathbb{R}$ is defined as

$$\rho(X, Y) = \frac{E(XY) - E(X)E(Y)}{\sqrt{\text{Var}(X)\text{Var}(Y)}}, \quad (1)$$

provided this quantity is well defined. The numerator in Eq. (1) is called “covariance.”

The main properties of Eq. (1) are:

Symmetry: $\rho(X, Y) = \rho(Y, X)$.

Boundedness: $-1 \leq \rho(X, Y) \leq 1$.

Invariance before linear transformations: For any $a, b \in \mathbb{R}$ holds that $\rho(aX + b, aY + b) = \rho(X, Y)$, and that $\rho(aX + b, -aY + b) = -\rho(X, Y)$.

If X and Y are independent, then they are uncorrelated, e.g., $\rho(X, Y) = 0$. The converse is not necessarily true, but if both X and Y are normal random variables, then it holds.

When X and Y belong to the same random process, Eq. (1) is called “autocorrelation.” In this case, instead of X and Y , one usually denotes the random variables with an index, e.g., X_t and X_u , and their correlation as $\rho_{t,u}$.

Discussion

Time Series

Consider an infinite series of real-valued random variables $X = (\cdots, X_{t-2}, X_{t-1}, X_t, X_{t+1}, X_{t+2}, \cdots)$. A general model allows both the mean $E(X_u) = \mu_u$ and the variance $\text{Var}(X_u) = \sigma_u^2$ to vary with the index u , and the covariance $\text{Cov}(X_u, X_v)$ to vary with the pair of indexes (u, v) .

We will make three assumptions in order to facilitate our presentation:

H1: The (finite) mean does not vary with the index: $\mu_u = \mu < \infty$ for every $u \in \mathbb{Z}$.

H2: The (finite) variance does not vary with the index: $\sigma_u^2 = \sigma^2 < \infty$ for every $u \in \mathbb{Z}$.

H3: The covariance depends only on the absolute value of the difference between the indexes: $\text{Cov}(X_u, X_v) = \text{Cov}_k$, where $k = |u - v|$ for every $(u, v) \in \mathbb{Z} \times \mathbb{Z}$. This absolute difference k is known as “lag,” and Cov_k is referred to as “autocovariance.”

A random process X that satisfies these three hypotheses is called “weakly stationary.”

The autocorrelation of X is

$$\rho_k = \frac{\text{Cov}_k}{\sigma^2} = \frac{\mathbb{E}[(X_{t+k} - \mu)(X_t - \mu)]}{\sigma^2}, \quad (2)$$

which, by the hypotheses above, does not depend on t . Notice that $\rho_0 = 1$.

Finlay et al. (2011) provide a comprehensive account of conditions for a function $\rho_k : \mathbb{Z} \rightarrow [-1, 1]$ to be a valid autocorrelation function (ACF). Such a characterization is primarily helpful for theoretical purposes.

In practice, one encounters finite time series $\mathbf{x} = (x_1, x_2, \dots, x_n)$ of length n , with which one has to make several types of inference. If we are interested in estimating the autocorrelation, we may use the estimator of the autocovariance

$$\widehat{\text{Cov}}_k = \frac{1}{n} \sum_{t=1}^{n-k} (x_t - \bar{\mathbf{x}})(x_{t+k} - \bar{\mathbf{x}}), \quad (3)$$

where $\bar{\mathbf{x}}$ is the sample mean of the whole time series, and then obtain the estimator of the autocorrelation

$$\hat{\rho}_k = \frac{\widehat{\text{Cov}}_k}{\widehat{\text{Cov}}_0}. \quad (4)$$

Notice that $\widehat{\text{Cov}}_0$ is the sample variance of the whole time series.

If $\rho_k = 0$, then $\hat{\rho}_k$ is asymptotically distributed as a Gaussian random variable with mean $-1/n$ and variance $1/n$. This result

provides a simple rule for building approximate confidence intervals around 0.

Figure 1 shows 1000 observations of atmospheric noise (top) collected by <https://www.random.org>, along with the first 30 estimates of its autocorrelation function (ACF) $\hat{\rho}_1, \hat{\rho}_2, \dots, \hat{\rho}_{30}$ and the approximate confidence interval at the 95% level. As expected for this kind of noise, there is no evidence of serial correlation.

Figure 2 shows 870 measurements of the daily number of sun spots (top) downloaded from <https://www.ngdc.noaa.gov/stp/solar/ssndata.html>, along with the first 29 estimates of its autocorrelation function (ACF) $\hat{\rho}_1, \dots, \hat{\rho}_{29}$ and the approximate confidence interval at the 95% level. Seasonal observations like these often show significant autocorrelation values.

The reader is referred to the texts by Gilgen (2006) for specific applications to geosciences, and to the more general books by Box et al. (1994), Cryer and Chan (2008), and Cowpertwait and Metcalfe (2009).

Extensions

Not rejecting a test for zero autocorrelation (or autocovariance) does not imply independence. Székely et al. (2007) discuss extensions (distance autocorrelation and distance covariance) which are zero only if the random vectors are independent.

Autocorrelation and autocovariance are defined over real-valued (univariate) random vectors. Székely and Rizzo (2009) define a new measure, the Brownian Distance Covariance, that compares vectors of arbitrary dimension.

Autocorrelation,

Fig. 1 Gaussian atmospheric noise

Autocorrelation,
Fig. 2 Number of sun spots

Summary

Autocorrelation functions are powerful tools for an exploratory analysis of the dependence structure of time series.

Automatic and Programmed Gain Control

Gabor Korvin

Earth Science Department, King Fahd University of Petroleum and Minerals, Dhahran, Kingdom of Saudi Arabia

Definition

In the electronic *acquisition* of geoscientific data, and their subsequent digital *processing*, we frequently subject the data to *Gain Control* which is a nonlinear transformation to maintain an approximately *stationary signal* of a prescribed Root Mean Square (RMS) amplitude at its output, despite time-dependent slow variations of the signal amplitude level at the input. In simple terms, Gain Control reduces the signal if it is strong and amplifies it when it is weak. There are two ways to control signal amplitude, *automatically* or in a preset, *programmed* manner. *Automatic Gain Control* (AGC, also called *Automatic Volume Control* (AVC), *Automatic Level Control* (ALC), *Time-Varying Gain* (TGC)) is realized by an algorithm where the output energy level in a sliding time-window controls the gain applied to the input to keep it within prescribed limits. *Programmed Gain Control* (PGC) applies a gain which is a function of record time and was determined beforehand. In some AGC or PGC systems the gain can only vary by a factor of two (*Binary Gain Control* BGC). Gain Control (AGC or PGC) is an important step of data processing to improve the visibility of such data where propagation effects (such as *attenuation* or *spherical divergence*) have

caused amplitude decay, and to assure approximate *stationarity* which is a prerequisite for *statistical time-series analysis*.

Introduction: Stationary and Nonstationary Processes, Gain Control

Before delving into the treatment of *Gain Control*, we must discuss the concepts of *stationarity* and *nonstationarity* of a *stochastic process*. Stationarity of a time series has become considered – paradoxically – of crucial importance in analyzing Earth data (Myers 1989), even though most dynamic geoprocesses (such as “expansion of the Universe, the evolution of stars, global warming on the Earth, and so on,” Guglielmi and Potapov 2018) are actually nonstationary. In simple terms, stationarity means that the statistical properties of a time series (more exactly: of the *stochastic process* generating the time series) do not change over time. In other words, a stationary time series has statistical properties (such as mean, variance, and autocovariance) that do not change under time translation. Stationary processes are easier to analyze, to display, to model, and their future behavior is in a certain sense predictable because their statistical properties will be the same in the future as they have been in the past. There are different notions of stationarity, such as (Myers 1989, Nason 2006): (a) *Strong stationarity* (also called *strict stationarity*) requires that the joint distribution of any finite sub-sequence of random variables of the process remains the same as we shift it along the time index axis: A stochastic process $\{Y_t\}_{t=-\infty}^{\infty}$ is strongly stationary if, for any integer n , and any set of time instants $\{t_1, t_2, \dots, t_n\}$ the joint distribution of the random variables $(Y_{t_1-t}, Y_{t_2-t}, \dots, Y_{t_n-t})$ depends only on $\{t_1, t_2, \dots, t_n\}$ but not on t . (b) *Weak stationarity* (also called *covariance stationarity*) only requires the shift-invariance of the mean and the autocovariance: a process is *weakly stationary* or *covariance stationary* if (letting E denote expected value).

$$\begin{aligned} E(Y_t) &= \mu \neq \pm\infty \quad \forall t \\ \text{var}(Y_t) &= \sigma^2 < \infty \quad \forall t \\ \text{cov}(Y_t, Y_{t-\tau}) &= E[(Y_t - \mu)(Y_{t-\tau} - \mu)] = \gamma_\tau \neq \pm\infty \quad \forall t, \forall \tau \end{aligned} \quad (1)$$

(c) In *geostatistics* (Myers 1989) they often assume an even weaker property than covariance stationarity, namely the so-called *intrinsic hypothesis* which assumes the stationarity of the semivariogram, and holds for a stochastic process $\{Y_t\}_{t=-\infty}^{\infty}$ if (i) the expected difference between values at any two time instants separated by a distance τ is zero: $E[Y_t - Y_{t-\tau}] = 0$ for $\forall \tau$ and (ii) the variance of these

differences, $\text{var}[Y_t - Y_{t-\tau}]$ is finite and depends only the distance τ .

A well-known example for a stationary process is the *White Noise process*: it is a stochastic process with a constant mean of zero and a constant and finite variance, whose values at any two different time instants are uncorrelated. Formally, the process $W = \{W_t\}_{t=-\infty}^{\infty}$ is a white noise if: $\forall t E(W_t) = 0$ (Eq. 2a); $\forall t E[(W_t - \mu)^2] = E(W_t^2) = \sigma^2 < \infty$ (Eq. 2b); $\forall t_1, t_2, t_1 \neq t_2 E(W_{t_1} \cdot W_{t_2}) = \text{cov}(W_{t_1}, W_{t_2}) = 0$ (Eq. 2c).

Note that this is a *weakly stationary process*. If, in addition, for every t the value W_t follows a normal distribution with zero mean and variance σ^2 , then the process is a *Gaussian White Noise process*. A White Noise process $\{\varepsilon_t\}_{t=-\infty}^{\infty}$ with zero mean and variance σ^2 is conveniently denoted as $\varepsilon_t \sim WN(0, \sigma^2)$ (if it is Gaussian, we write $\varepsilon_t \sim GWN(0, \sigma^2)$). Using such a process, we can recursively construct a famous *nonstationary* process, the so-called *Random Walk*, for the time instants $t = 0, 1, 2, \dots$, as follows: Let Y_0 be an arbitrary real number, and $\forall t Y_t = Y_{t-1} + \varepsilon_t$. We get, step by step, for $t = 1, 2, \dots$ that $Y_1 = Y_0 + \varepsilon_1$; $Y_2 = Y_1 + \varepsilon_2 = Y_0 + \varepsilon_1 + \varepsilon_2$; $\dots$; and $Y_n = Y_0 + \sum_{i=1}^n \varepsilon_i$ (Eq. 3). Using Eq. 3 and the properties (Eqs. 2a, b, c) of $\{\varepsilon_t\}_{t=-\infty}^{\infty}$, easy calculation gives that $E(Y_n) = Y_0$ (Eq. 4a) which is independent of the time-variable n ; however, the variation $\text{var}(Y_n) = E\left[\left(\sum_{i=1}^n \varepsilon_i\right)^2\right] = n \cdot \sigma^2$ (Eq. 4b) increases with n , that is the random walk $\{Y_0, Y_1, \dots\}$ is not stationary.

A frequently occurring type of nonstationary processes are those having a *deterministic trend* (or “drift”). For example, let s_t be stationary with zero mean, α, β given constants, then the process $Y_t = \alpha + \beta t + s_t$ (Eq. 5) is nonstationary, because its mean $E(Y_t) = \alpha + \beta t$ depends on t . This kind of nonstationarity can be easily eliminated if we find α, β by *least mean square fitting*, and then simply subtract off the trend: $X_t = Y_t - \alpha - \beta t \approx s_t$ (Eq. 6). (Here, the approximate equality, “ $\approx$ ”, sign is a reminder of the issues arising from the uncertainty in the fitting.)

Usually, the nonstationary processes that we encounter in Geosciences cannot be such easily transformed into stationary processes. Sometimes a nonstationary time-series consists of a number of time segments that are themselves stationary. Such a time-series could be easily transformed to a stationary one by finding, and eliminating, the individual mean values of the segments, and then determining the proper multiplying factors to equalize the variances. Alas, no feasible computational algorithm has been found yet to find these locally stationary segments and locate their boundaries (Fukuda

et al. 2004), even to decide whether a segment of a time-series is stationary or not is a hot research question in statistics (Palachy 2019).

In many cases records of Earth processes and geophysical signals are described by *locally stationary* (LS) processes (Nason 2006). Around each time point they are close to a stationary process but their local mean and covariance are slowly changing in an *unspecific* way as time evolves. Such a record can be modeled as $x(t) = a(t) + \beta(t)s(t) + \varepsilon(t)$ (Eq. 7) where $x(t)$ is the observed LS process, $a(t)$ is a *slowly varying additive drift*, $\beta(t)$ is a *slowly varying* strictly positive *multiplying factor*, $s(t)$ is the original, stationary signal with zero mean value and unit variance, and $\varepsilon(t) \sim WN(0, \sigma^2)$ is additive white noise which is uncorrelated with $s(t)$. The drift $a(t)$ can be eliminated by *differencing* (as in Eq. 6) or by HP (high pass) *filtering*, then the record transforms to $x^*(t) \approx \beta(t)s(t) + \varepsilon^*(t)$ (Eq. 8), where $\varepsilon^*(t) \sim WN(0, \sigma_1^2)$ is the transformed noise. If $\beta(t)$ is known (from visual observation, or physical arguments) and we can assume that for $\forall t$ we have $|\sigma_1| \ll \beta(t)$ (Eq. 9), then the stationary, normalized, zero-mean earth signal $s(t)$ can be estimated from Eq. 8 as $s(t) \approx \frac{x^*(t)}{\beta(t)}$ (Eq. 10). This procedure is called *Programmed Gain Control* (PGC), and – importantly – it requires the knowledge of $\beta(t)$. PGC will be discussed, for the case of seismic data, in the next

Sect. 2. If $\beta(t)$ is not known, first of all we have to estimate it from Eq. 8, and then apply it as in Eq. 10 to find $s(t)$. This procedure is called *Automatic Gain Control* (AGC), and will be discussed in Sect. 3. Examples for both kinds of gain will be taken from *seismic data processing*.

Programmed Gain Control (“True Amplitude Recovery”) of Seismic Data

Without any gain control the seismic amplitudes for large arrival times, and/or large offsets, would be too small to display. Compare the two seismic profiles on Fig. 1, the left without, the right with, amplitude regulation.

The decay of seismic amplitudes with time, illustrated in Fig. 2, has many reasons, such as *geometric spreading*, *reflection losses* at boundaries, *inelastic absorption*, *wave conversion* ($P \rightarrow S$, $S \rightarrow P$) at oblique incidence, energy scattered out of the wave path, etc. Because of these effects the seismic amplitude soon sinks below the ambient noise level. An important seismic processing step, *True Amplitude Recovery* applies a special *Programmed Gain Control* to the recorded traces to compensate for amplitude losses caused by *wavefront spreading* and *attenuation*. Seismic processing

Automatic and Programmed Gain Control, Fig. 1 Seismic profile without, and with, Automatic Gain Control

Automatic and Programmed Gain Control, Fig. 2 Amplitude decay of seismic data due to propagation effects

software packages offer a number of gain control possibilities to correct for spherical divergence and inelastic attenuation effects.

Geometric spreading means that the energy of the source is spread over a hemisphere in case of isotropy and constant velocity, or over a surface of more complicated shape in anisotropic formations (Newman 1973, Yilmaz 2001), that is the average RMS amplitude decays as $\sim 1/\text{distance}$ $\sim \frac{1}{[t_0 v(t_0)/\tau v(\tau)]}$ where t_0 is 2-way travel-time, $v(t_0)$ the RMS stacking velocity, τ some arbitrary time instant; that is the multiplicative gain to compensate this effect is $g(t_0) = \text{const} \cdot [t \cdot v(t_0)t_0 v(t_0)/\tau v(\tau)]$ (Eq. 11a). Some companies use a gain $g(t_0) = \text{const} \cdot [t_0 v^2(t_0)/\tau v^2(\tau)]$ (Eq. 11b) instead. There also exists an other kind of geometric loss, the *reflection loss*. If a wave crosses two times a boundary with reflection coefficient r_i , once downwards and once upwards, both times at normal incidence, the wave amplitude gets reduced by a factor $1 - r_i^2$, where $\{r_i\}, E(r_i) = 0, \text{var}(r_i) = E(r_i^2) = r^2 \ll 1$ is the series of *reflection coefficients*. Assuming that the reflecting boundaries are *Poisson-distributed* in a sense that a number λ of them are crossed by the propagating wave during one sec two-way time, the reflection loss is exponential: $\text{loss}_{\text{refl}} = \exp(-\lambda r^2 t_0)$ (Eq. 12). Combining this with the inelastic loss $\text{loss}_{\text{absorption}} = \exp(-\alpha t_0)$ where α is the *absorption coefficient*, the total decay is $\text{loss}_{\text{total}} = \exp(-\beta t_0)$ where $\beta = \lambda r^2 + \alpha$, and to compensate it one needs a predetermined gain $g(t_0) = \text{const} \cdot \exp(\beta t_0)$ (Eq. 13). In some processing software (as, e.g., ProMAX[®] 2004) the gain Eq. 13 can be also specified in dB/sec units in the form $g(t_0) = \text{const} \cdot 10^{C t_0/20}$ (Eq. 14) where the gain-factor C is in dB/sec. The Programmed Gain to compensate both for wave-front spreading and attenuation is $g(t_0) = \text{const} \cdot [t \cdot v(t_0)t_0 v(t_0)/\tau v(\tau)] \cdot \exp(\beta t_0)$ (Eq. 15). If the RMS stacking velocity $v(t_0)$ and the attenuation factor β are not known, we resort to the approximate, heuristic “Time Power compensation,” realized by $g(t_0) = \text{const} \cdot t_0^\gamma$ (Eq. 16) where in seismic practice the exponent γ is between 1 and 2, by default $=2$. The *normalizing factors* in Eqs. 11 a, b; 13; 14; 15; 16 are used to maintain a prescribed RMS amplitude

Automatic and Programmed Gain Control, Fig. 3 Time-variant scaling of a seismic trace

level, as well as for *trace balancing* if a group of traces are jointly subjected to PGC. By proper selection of these factors, each trace in the group of traces can be scaled so that they all have the same desired RMS amplitude level.

Automatic Gain Control (AGC)

The easiest way to subject a group of seismic traces to AGC is to apply *time-variant scaling* (Fig. 3). As seen in the Figure, we (i) divide all traces in the group to N time segments (“windows”) of equal length, each having K samples; (ii) compute the local mean value $\mu_i = \frac{1}{K} \sum_{n \in W_i} x_n$ in each window W_i and subtract it from the relevant data; (iii) compute the RMS (Root Mean Square) amplitude for each window: $a_i = \sqrt{\frac{1}{K} \sum_{n \in W_i} (x_n - \mu_i)^2}$; construct a smooth function $a(t)$ (with *spline approximation*) passing through the points $a(t_1) = a_1, a(t_2) = a_2, \dots, a(t_N) = a_N$ where $t_1, t_2, \dots, t_N$ are midpoints of the windows; (iv) take the average of the $a(t)$ curves over all traces to get an average decay curve $A(t)$ (see the second curve in Fig. 3); and (v) apply the gain $g(t) = \frac{\text{const}}{A(t)}$ (Eq. 17). Figure 3 illustrates this on a single seismic trace.

A similar, but more powerful AGC algorithm utilizes *sliding windows* to avoid sudden jumps in the gain curve. Automatic gain control (AGC) is the most common way of gain recovery in seismic processing. AGC is applied to the seismic data on a trace-by-trace basis using a sliding time window of length $N \cdot \Delta t$ (Δt is the sampling interval, in seismic practice, usually 2 or 4 msec, N is of the order 50). The window is progressively moved along the time axis

sample-by-sample. Suppose the window consists of $N = 2M + 1$ data, the seismic values $\{x_i\}$ are sufficiently well “de-measured” (i.e., their local mean value had been removed by High Pass filtering), such that for $\forall i = 1, 2, \dots, M \leq i \leq RL - M$ where RL is record length in Δt units, we have $\frac{1}{2M+1} \sum_{k=i-M}^{i+M} x_k \approx 0$ (Eq. 18). Then, for all i the average energy within the moving window $W_i = \{i-M, i-M+1, \dots, i-M+1, i-M+1, \dots, i-1, i, i+1, \dots, i+M-1, i+M\}$ is computed as $E_i = \frac{1}{2M+1} \sum_{k=i-M}^{i+M} x_k^2$ (Eq. 19), and the sample x_i in the center of this window is divided by this energy to yield the result of AGC: $y_i = \frac{1}{\frac{1}{2M+1} \sum_{k=i-M}^{i+M} x_k^2} \cdot x_i = g(i) \cdot x_i$ (Eq. 20),

where $g(i) = \frac{1}{E_i}$ is the gain factor. Instead of average energy (E_i , see Eq. 19) we could also use *RMS amplitude* $A_{RMS,i} = \sqrt{\frac{1}{2M+1} \sum_{k=i-M}^{i+M} x_k^2}$, *average absolute amplitude* $A_{abs,i} = \frac{1}{2M+1} \sum_{k=i-M}^{i+M} |x_k|$, or *median absolute amplitude* $A_{med,i} = \text{median}\{|x_i - M|, \dots, |x_i|, \dots, |x_i + M|\}$ (Eqs. 21 a,b,c) to construct a gain function $g(i)$.

AGC can be *fast* or *slow*. A very short window might eliminate geologically meaningful amplitude variations, and does not necessarily fulfill condition (Eq. 18). The processing geophysicist must ensure that the window is long enough to include many reflectors so that their relative amplitude ratio should remain visible after gain regulation.

A Few Concluding Remarks on the Use of PGC and AGC

- (i) In the 1950s and before the analog seismic recorders used PGC. When digital recorders became widespread in the 1960s they already used digital *BGC* (*Binary Gain Control*), but they needed analog *preamplifiers* and an *analog PGC unit* to fully utilize the limited dynamic range of their *AD* (*Analog-to-Digital*) *converters*. Modern recorders use *IFP* (*instantaneous-floating-point*) *gain control*, where the gain is independently determined for each sample on each channel, based on the amplitude of that sample without reference to earlier samples or other channels.
- (ii) Automatic Gain Control must be used with utmost care, since it can destroy signal character. In seismics, an AGC with a very short sliding window makes strong reflections indistinguishable from weak reflections.
- (iii) If we want to preserve the relative amplitude ratios between nearby seismic traces, as for example when we pre-process our seismic material for *AVO* (*Amplitude versus Offset*) studies to find lithologic information from

seismic amplitudes, then no gain control at all, or only some very carefully designed PGC should be used.

- (iv) Some rock physical properties (such as electric- and heat conductivity and hydraulic permeability) have such a huge dynamic range that only their logarithms can be displayed as functions of depth (as, e.g., an electric well log trace). Such records of logarithmic data might look stationary, but the “log transform,” that is taking the logarithm of the data, is not the proper way, and not recommended, to improve the stationarity of a time series!

Definition

X-Ray computed tomography (CT) can visualize the internal structures of any material in three dimensions. Due to its capability of 3D visualization in a non-destructive fashion, it has found its application in various fields like material, geological, food, and paleontological sciences (Withers et al. 2021) [2, 10]. For instance, X-Ray microCT has revolutionized the field of Digital Rock Physics (Balcewicz et al. 2021) [1] by drastically reducing the decision time, compared to special core analysis laboratory (SCAL) measurements to estimate all the rock properties. Backprojection is one of the oldest and simplest reconstruction methods which exist in literature. In seismology, a simple backprojection algorithm has been applied to generate tomographic images of P-velocity or the seismic transparency for the section of rock between the borehole (Wong et al. 1983) [9]. Although backprojection method is not practically adopted in its basic form for reconstruction, it still continues to form the basis of various practically used reconstruction algorithms. One of the commonly adopted reconstruction algorithms is the filtered backprojection algorithm which is the main focus of this chapter. Filtered backprojection algorithm belongs to a class of analytical reconstruction techniques and has been widely adopted due to its ease of implementation and reconstruction speed.

Introduction

Tomographic image reconstruction is a problem where a 3-D object is reconstructed from its 2-D projections. One way to obtain projections is through transmission of a beam that passes through the object and is detected at the other end through an array of detector elements.

The intensity of the beam measured at the detector depends on the material through which the beam passes and is attenuated by the material by the formula

$$\frac{I}{I_0} = e^{-\int \alpha ds}$$

where I_0 is the intensity of the beam at the source that is incident on the object, α is the local linear attenuation, and s is the path along which the beam travels. The attenuation constant is a material property dictated by absorption and scattering. The source and detector are 180 degrees apart and form a part of a single assembly. This assembly is rotated to obtain projections at different angles.

Practical arrangements of the source–detector assembly differ and are of primarily three types:

- Parallel-beam tomography.
- Fan-beam tomography.
- Cone-beam tomography.

We have described algorithms for all the three source-detector assembly along with their mathematical formulation in the subsequent sections.

Parallel-Beam Image Reconstruction

Here, we describe the parallel-beam reconstruction algorithm, which form the basis for deriving the results for the more complex and practically used setup – fan-beam reconstruction

and cone-beam reconstruction algorithms. In what follows, we will learn about radon transform, followed by Fourier slice theorem and filtered backprojection (FBP) algorithm.

Radon Transform

Backprojection-based tomographic reconstruction technique can be mathematically explained in terms of radon transform (initially proposed for astronomical-based application in 1917) (Radon 1917; Ludwig 1966). Radon transform expresses the function values ($f(x, y)$) in terms of projection data ($g_\theta(x')$), which is nothing but a line integral. Given a 2-D object, $f(x, y)$ under study can also be expressed in the rotated coordinate system by $s(x', y')$ (see Fig. 1). Following this notation, we present the mathematical formulation for the radon transform subsequently. A line integral will represent the ray sum/integral of $f(x, y)$ along a given line. For CT based application, this ray sum represents the total attenuation that the X-rays undergo while passing through the object under study. Each line integral can be easily expressed in terms of two parameters (θ, x'), where θ represents the angle at which X-rays are projected onto the object or the angle at which the detector is aligned to measure X-ray attenuation. Line integral ($g_\theta(x')$) is expressed as.

$$g_\theta(x') = \int_{y'=-\infty}^{\infty} s(x', y') dy' \quad (1)$$

The relation between $x - y$ coordinate system and the rotated $x' - y'$ coordinate system can be easily expressed using rotation matrices ($A_\theta/A_{-\theta}$) as

$$\begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix} \begin{bmatrix} x' \\ y' \end{bmatrix} = A_\theta \begin{bmatrix} x' \\ y' \end{bmatrix} \quad (2)$$

$$x = x' \cos \theta - y' \sin \theta \text{ \& } y = x' \sin \theta + y' \cos \theta$$

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = A_{-\theta} \begin{bmatrix} x \\ y \end{bmatrix} \quad (3)$$

$$x' = x \cos \theta + y \sin \theta \text{ \& } y' = -x \sin \theta + y \cos \theta$$

Using Eqs. 2 and 3, we can easily express the object $f(x, y)$ in the rotated $x' - y'$ coordinated axis as

$$\begin{aligned} f \begin{bmatrix} x \\ y \end{bmatrix} &= f(x, y) = f(x' \cos \theta - y' \sin \theta, x' \sin \theta + y' \cos \theta) \\ &= s(x', y') \end{aligned} \quad (4)$$

Combining Eq. 4 with Eq. 1, we arrive at the final expression of the radon transform expressed as

Backprojection Tomography,

Fig. 1 Illustration of the geometry of a set of parallel projection beams

$$\begin{aligned}
 g_\theta(x') &= \int_{y'=-\infty}^{\infty} f(x' \cos \theta - y' \sin \theta, x' \sin \theta + y' \cos \theta) dy' \\
 &= \int_{y'=-\infty}^{\infty} f\left(A_\theta \begin{bmatrix} x' \\ y' \end{bmatrix}\right) dy'
 \end{aligned} \quad (5)$$

where $g_\theta(x')$ is the radon transform of the object function $f(x, y)$ and graphic representation of radon transform known as sinogram in the CT imaging terminology.

Fourier Slice Theorem

In this section, we will learn about another vital concept needed to understand the backprojection reconstruction algorithm. Using Fourier slice theorem (Herman 1979, 1980; Scudder 1978), we establish the relation between the 1-D continuous-time Fourier transform (CTFT) of $g_\theta(x')$ and 2-D CTFT of the object $f(x, y)$ (see Fig. 2). We start the derivation by expressing Fourier transforms of $g_\theta(x')$ & $f(x, y)$ as

$$\begin{aligned}
 f(x, y) &\xrightarrow{\text{2D-CTFT}} F(w_x, w_y) \\
 &= \int_{x=-\infty}^{\infty} \int_{y=-\infty}^{\infty} f(x, y) e^{-j2\pi(w_x x + w_y y)} dx dy \quad (6)
 \end{aligned}$$

$$g_\theta(x') \xrightarrow{\text{1D-CTFT}} G_\theta(w) = \int_{x'=-\infty}^{\infty} g_\theta(x') e^{-j2\pi w x'} dx' \quad (7)$$

Further, using radon transform (Eq. 5), we can express $G_\theta(w)$ in terms of $f\left(A_\theta \begin{bmatrix} x' \\ y' \end{bmatrix}\right)$ as.

$$\begin{aligned}
 G_\theta(w) &= \int_{x'=-\infty}^{\infty} \left(\int_{y'=-\infty}^{\infty} f\left(A_\theta \begin{bmatrix} x' \\ y' \end{bmatrix}\right) dy' \right) e^{-j2\pi w x'} dx' \\
 &= \int_{x'=-\infty}^{\infty} \int_{y'=-\infty}^{\infty} f\left(A_\theta \begin{bmatrix} x' \\ y' \end{bmatrix}\right) e^{-j2\pi w x'} dx' dy'
 \end{aligned} \quad (8)$$

We now apply the change of variable to the above integral using the relation expressed in Eq. 3 as

$$f\left(A_\theta \begin{bmatrix} x' \\ y' \end{bmatrix}\right) = f\left(A_\theta A_{-\theta} \begin{bmatrix} x \\ y \end{bmatrix}\right) = f\left(\begin{bmatrix} x \\ y \end{bmatrix}\right) = f(x, y) \quad (9)$$

After applying the change of variable, we express Eq. 8 completely in terms of $x - y$ coordinate system as

$$G_\theta(w) = \int_{x=-\infty}^{\infty} \int_{y=-\infty}^{\infty} f(x, y) e^{-j2\pi w (x \cos \theta + y \sin \theta)} dx dy \quad (10)$$

Comparing Eq. 10 with Eq. 6, we derive the following equation:

$$G_\theta(w) = F(w \cos \theta, w \sin \theta) \quad (11)$$

The relation expressed in Eq. 11 is called Fourier slice theorem.

Backprojection Tomography, Fig. 2 Illustration of Fourier slice theorem

Filtered Backprojection Algorithm

We now describe the FBP algorithm that aims to recover the actual object $f(x, y)$ from the corresponding tomographic projections ($g_\theta(x')$) data. Object function $f(x, y)$ can be expressed using inverse CTFT relation as

$$f(x, y) = \int_{x=-\infty}^{\infty} \int_{y=-\infty}^{\infty} F(w_x, w_y) e^{j2\pi(w_x x + w_y y)} dw_x dw_y \quad (12)$$

We now apply the change of variable to the above integral using the following relation:

$$\begin{aligned} w_x &= w \cos \theta, w_y = w \sin \theta \\ dw_x dw_y &= |w| dw d\theta \end{aligned} \quad (13)$$

This results in the following equation:

$$f(x, y) = \int_{\theta=0}^{\pi} \int_{w=-\infty}^{\infty} F(w \cos \theta, w \sin \theta) e^{j2\pi w(x \cos \theta + y \sin \theta)} |w| dw d\theta \quad (14)$$

Using Fourier slice theorem (Eqs. 11 and 3), we get

$$f(x, y) = \int_{\theta=0}^{\pi} \left(\int_{w=-\infty}^{\infty} |w| G_\theta(w) e^{j2\pi w x'} dw \right) d\theta \quad (15)$$

where $|w|$ corresponds to a convolution in spatial domain. We define inverse Fourier transform of $|w|$ as $h(x')$. In spatial domain, Eq. 15 can be expressed as.

$$f(x, y) = \int_{\theta=0}^{\pi} (h(x') \otimes g_\theta(x')) \Big|_{x'=x \cos \theta + y \sin \theta} d\theta \quad (16)$$

which represents the sum of all the measured projection data ($g_\theta(x')$) convoluted ($\otimes$) with $h(x')$.

Complete FBP algorithm can be summarized as follows:

- Compute $g_\theta(x')$ for each projection of the object ($f(x, y)$).
- Convolve the each projection result as follows:

$$b_\theta(x') = (h(x') \otimes g_\theta(x'))$$

- Backproject all the above obtained filtered projections by computing

$$f(x, y) = \int_{\theta=0}^{\pi} b_\theta(x') \Big|_{x'=x \cos \theta + y \sin \theta} d\theta$$

Fan-Beam Image Reconstruction

The FBP algorithm described for the parallel-beam geometry is a robust and fast way of reconstructing the slices from the tomographic projection data. But at the same time, implementing a parallel-beam setup requires the installation of bulky hardware and needs the object to be exposed for a more extended period under an X-ray source. Using fan-beam geometry, it is possible to cleverly reduce the long acquisition time and avoid the need for bulky hardware. In the following sections, we will discuss two techniques, along with the mathematical framework, involved in fan-beam image reconstruction.

Reconstruction with Rebinning

In parallel-beam geometry, we use Fourier slice theorem to derive the FBP reconstruction algorithm. But, in the case of fan-beam geometry, we do not enjoy the luxury of any such theorem to derive reconstruction algorithms. Hence, we use a different strategy – converting a fan-beam geometric model to its equivalent parallel-beam geometric model. Figure 3 shows the comparison of two imaging geometries. It is intuitively evident that both parallel-beam and fan-beam geometries cover identical data in one complete rotation. The only difference lies in the data collection sequence in both the setups. Hence, once the entire data is collected in the fan-beam setup, we can rebin the entire data sequence in such a fashion so that the new data sequence corresponds as if the data was collected using a parallel-beam setup. Rebinning every fan-beam ray ($p(\gamma, \beta)$) into a parallel-beam ray ($g_\theta(x')$) is mathematically explained using Fig. 4a). The following relation can be easily established using a couple of mathematical steps:

$$\theta = \gamma + \beta \quad (17)$$

and

$$x' = D \sin \gamma \quad (18)$$

Using the above relation, we can conveniently convert parallel-beam ray sum into fan-beam ray sum and vice versa:

$$g_\theta(x') = p(\gamma, \beta) \quad (19)$$

After rebinning is completed, one can use FBP algorithm for parallel-beam geometry to perform image reconstruction.

Backprojection Tomography,**Fig. 3** Comparison of imaging geometries: (a) parallel-beam geometries; (b) fan-beam geometries**Backprojection Tomography, Fig. 4** (a) Conversion of fan-beam ray parameters into its corresponding parallel-beam ray parameters; (b) coordinate system for fan-beam imaging geometry**Reconstruction without Rebinning**

However, rebinning of fan-beam rays into parallel-beam rays is not a preferred technique as it requires the data interpolation while changing the coordinates. This data interpolation often leads to inaccurate image reconstruction. But with the relation described in Eqs. 17 and 18, we can derive the analytical reconstruction solution in terms of fan-beam geometry parameters. The technique is referred to as the “filtered back-projection fan-beam algorithm” (Weng et al. 1997) and will be described in the following section.

Filtered Backprojection fan-Beam Algorithm

We start the derivation with the final reconstruction equation obtained using FBP for the parallel-beam geometry, which is

$$f(x, y) = \frac{1}{2} \int_{\theta=0}^{2\pi} (h(x \cos \theta + y \sin \theta) \otimes g_{\theta}(x \cos \theta + y \sin \theta)) d\theta \quad (20)$$

where $\otimes$ denotes the convolution operator. We now express the above equation in the polar coordinate system by replacing $x = r \cos \phi$, $y = r \sin \phi$ and $x \cos \theta + y \sin \theta = r \cos(\theta - \phi)$, resulting in

$$f(r, \phi) = \frac{1}{2} \int_{\theta=0}^{2\pi} \int_{-\infty}^{\infty} g_{\theta}(x') h(r \cos(\theta - \phi) - x') dx' d\theta \quad (21)$$

Changing the variables of the above integral using Eqs. 17 and 18 by using the Jacobin required for variable change as $D \cos \gamma$ results in

$$f(r, \phi) = \frac{1}{2} \int_{\theta=0}^{2\pi} \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} p(\gamma, \beta) h(r \cos(\beta + \gamma - \phi) - D \sin \gamma) D \cos \gamma d\gamma d\beta \quad (22)$$

Equation 22 represents the analytical solution for the fan-beam geometry. But still it is not computationally efficient due to the absence of convolution operation. Next, we describe how convolution operation can be introduced in the

final solution, making it computationally efficient to implement.

We define two new parameters D' and γ' (see Fig. 4b) totally with respect to the point being reconstructed ($f(r, \phi)$). From Fig. 4b, we can derive the following relation:

$$r \cos(\beta + \gamma - \phi) - D \sin \gamma = D' \sin(\gamma' - \gamma)$$

which yields

$$f(r, \phi) = \frac{1}{2} \int_{\theta=0}^{2\pi} \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} p(\gamma, \beta) h(D' \sin(\gamma' - \gamma)) D \cos \gamma \, d\gamma \, d\beta \quad (23)$$

We now state a special property of a ramp filter (Eq. 24) and use it to arrive at the final solution:

$$h(D' \sin(\gamma)) = \left(\frac{\gamma}{D' \sin \gamma} \right)^2 h(\gamma) \quad (24)$$

If $h_{fan}(\gamma) = \frac{D}{2} \left(\frac{\gamma}{\sin \gamma} \right)^2 h(\gamma)$, then the final convolution-based fan-beam backprojection solution (Eq. 25) is stated as

$$f(r, \phi) = \int_{\theta=0}^{2\pi} \frac{1}{(D')^2} \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} (\cos \gamma) p(\gamma, \beta) h_{fan}(\gamma' - \gamma) d\gamma \, d\beta \quad (25)$$

Cone-Beam Image Reconstruction

Cone-beam geometry-based reconstruction algorithm, in general, is considered to be more complex in comparison to parallel- or fan-beam geometry. But at the same time they are extremely popular and accurate in terms of reconstructed image quality. In the next section, we describe ‘‘Feldkamp’s algorithm,’’ which is one of the popular reconstruction methods in reconstruction community.

Feldkamp’s Algorithm

Feldkamp’s cone-beam reconstruction technique (also referred to as FDK algorithm) (Feldkamp et al. 1984) is basically the modification of fan-beam FBP algorithm. The coordinate system followed for implementing the algorithm is described in Fig. 5. We start by writing the FBP solution for fan-beam geometry with the flat detector in the polar coordinates (Fig. 5a) as

$$f(r, \phi) = \frac{1}{2} \int_{\theta=0}^{2\pi} \frac{D}{D - x'} \int_{-\infty}^{\infty} \frac{D}{\sqrt{D^2 + l^2}} p(l, \beta) h(l' - l) dl \, d\beta \quad (26)$$

where $h(l)$ represents the ramp filter, D represents the focal length, $g(l, \beta)$ is the fan-beam projection ray sum, l represents

Backprojection Tomography, Fig. 5 (a) Coordinate system followed for fan-beam geometry with flat detector; (b) coordinate system followed while implementing Feldkamp’s cone-beam algorithm

a linear coordinate on the flat detector, and $x' = r \sin(\phi - \beta)$ and $l' = \frac{Dr \cos(\phi - \beta)}{D - r \cos(\phi - \beta)}$.

Fan-beam algorithm can be modified into Feldkamp's algorithm if the backprojection operation is a cone-beam backprojection (see Fig. 5b). The filtering is carried out in a row-wise fashion. It is to be noted that no filtering is performed in the axial direction (z). The final Feldkamp's algorithm can be represented as

$$f(r, \phi, z) = \frac{1}{2} \int_{\theta=0}^{2\pi} \frac{D}{D - x'} \int_{-\infty}^{\infty} \frac{D}{\sqrt{D^2 + l'^2 + z^2}} p(l, \hat{z}, \beta) h(l' - l) dl \, d\beta \quad (27)$$

where $p(l, \hat{z}, \beta)$ is the cone-beam projection. All the other parameters are described in Fig. 5b.

Summary and Conclusions

This chapter covered computational reconstruction methods for all three geometries (Parallel-Beam, Fan-Beam & Cone-Beam). These methods are one of the prominent techniques and fall under a standard bucket of analytical reconstruction techniques. Due to their fast reconstruction output compared to iterative reconstruction methods, they have been widely adopted in many fields of geoscience like determining the porosity, permeability, and various other fluid flow properties in petroleum geology, rock mechanics, and soil science (Schlüter et al. 2020; Mees et. al 2003) [7, 8].

Bayes's Theorem

Konstantinos Modis

School of Mining and Metallurgical Engineering, National Technical University of Athens, Athens, Greece

Synonyms

Bayes's law; Bayes's rule

Definition

In probability theory, Bayes's theorem can be formally stated according to the following equation:

$$P(\mathcal{A}|\mathcal{B}) = \frac{P(\mathcal{B}|\mathcal{A})P(\mathcal{A})}{P(\mathcal{B})} \quad (1)$$

where $\mathcal{A}$ and $\mathcal{B}$ are events, $P(\mathcal{A})$ and $P(\mathcal{B})$ are the probabilities of these events to occur with $P(\mathcal{B}) \neq 0$, and $P(\mathcal{A}|\mathcal{B})$ and $P(\mathcal{B}|\mathcal{A})$ are the conditional probabilities that $\mathcal{A}$ given $\mathcal{B}$ and $\mathcal{B}$ given $\mathcal{A}$ occur, respectively (Papoulis and Pillai 2002).

Application to Mineral Exploration or a “Mineral Adventure”

In mineral exploration, managers are often called upon to take decisions in extremely uncertain environments. As an example, consider the CEO of a small company that has been appointed to investigate an area where indications show that an economically interesting orebody may occur. On this account, the company is about to start the mineral exploration activities from the preliminary phase up to a pilot mine excavation and trial exploitation of the mineralization

Bayes's Theorem, Fig. 1 In the Mineral Exploration context, Bayes's theorem is used to enhance our knowledge on the mineralization by gradually assimilating new information coming from indirect or inexact sources. The screenshot is from "Mineral Adventure," a simulation game developed by National Technical University of Athens in the framework

of EU-funded "Virtual Mine" project (<https://virtualmine.net/>). You can practice strategic decision-making with Bayes's theorem in Mineral Exploration by playing this game in <http://geostatistics.eu/exercise-en.php#>

(Fig. 1). Moreover, since this is a step-by-step procedure, there is always the option to terminate the development of the project in the case it is no longer cost-effective, based on evidence.

An overview of the recorded experience on similar setups and a consultant geologist's advice says that the à priori probability of finding an economic mineralization may be up to 55%. Because this probability is not satisfactory and in order to increase the level of confidence on the presence of the deposit, the CEO considers the option to conduct first a geophysical survey of the subsurface, which, as also shown by experience, has a reliability of 80%. After reasonable thinking, he chooses to proceed on the exploration. This judgment pays back with a positive result.

At this point, the company has to decide whether to proceed to the next step of the exploration, which is to start a drilling campaign in order to collect real samples from the subsurface. But this decision is difficult because drilling might be very expensive. The CEO has to convince the board of directors that the new evidence is sufficient to support this decision (or is not?). How will he estimate the updated probability of the existence of the orebody? How can the new information be incorporated into the already accumulated knowledge? Bayes's theorem can solve this problem.

Consider translating event $\mathcal{A}$ from Eq. 1 as the existence of an orebody in the area under exploration and event $\mathcal{B}$ as the result of the geophysical campaign (positive or negative for

simplicity). Then, $P(\mathcal{A})$ is the à priori or prior probability of existence (which means before the present study), and $P(\mathcal{A}|\mathcal{B})$ is the updated (with the geophysical measurements) or the posterior probability of existence. Furthermore, $P(\mathcal{B}|\mathcal{A})$ can be conveniently translated as the likelihood of the data (geophysical measurements) and, finally, $P(\mathcal{B})$ as the total probability that geophysical exploration will give a positive result, that is, a constant number that ensures that the output will always be between 0 and 1. In this line, Bayes's theorem can be written as

$$\text{Posterior probability} = \frac{\text{Prior probability} \times \text{Likelihood of the data}}{\text{Normalization constant}} \quad (2)$$

According to the above, the normalization constant $P(\mathcal{B})$ has to be estimated first. By the total probability theorem (Papoulis and Pillai 2002),

$$P(\mathcal{B}) = P(\mathcal{B}|\mathcal{A})P(\mathcal{A}) + P(\mathcal{B}|\mathcal{A}')P(\mathcal{A}') \quad (3)$$

where $\mathcal{A}'$ is the complementary event of $\mathcal{A}$, i.e., a deposit does not exist.

After substitution in Eq. 3, we get

$$P(\mathcal{B}) = 0.8 \times 0.55 + 0.2 \times 0.45 = 0.53 \quad (4)$$

Inserting this probability into Bayes's theorem, we finally obtain the updated probability of existence:

$$P(\mathcal{A}|\mathcal{B}) = \frac{0.8 \times 0.55}{0.53} = 0.83 \quad (5)$$

What unveils here is that Bayes's theorem is a valuable tool to assimilate the newly gained information into the knowledge base. In this example, since the geophysical method used is reliable, the belief that a deposit may exist is substantially improved, and now it is reasonable to proceed to the drilling campaign.

Application to Geological Systems Modeling or "Like Oil and Water"

Modeling of geological systems like groundwater tables or petroleum reservoirs is typical in geosciences (Pyrz and Deutsch 2014). The scope of modeling (or simulation or forward problem) is to predict the response of the system to certain external stimuli. For example, in a petroleum reservoir, we would like to know the flow characteristics of oil in a certain production well. The usual difficulty in modeling a geological system is the inadequate knowledge of the parameters of the physical law representing its response to the stimulation. This is because these parameters are in general some regionalized quantities referring to soil or rock mass properties, and thus they may present large variability from site to site. In the inverse problem, the results of a set of measurements are used in order to infer the actual values of the parameters characterizing the geological system. But, although the forward problem normally has a unique solution, the inverse problem has not. This characteristic is referred to as "ill-posedness" and is the main reason why stochastic methods are preferable in order to solve the inverse problem (Tarantola 2005). Instead of focusing on exact numbers, by representing the spatial parameter field with a random function, the idea is to estimate intervals containing the real values of the parameters, given some uncertain measurements of system response.

Summarizing the above in a mathematical notation, the model of a physical system g with boundary conditions $\mathbf{u}$ can be described by its parameter set $\mathbf{m} = \{m_1, \dots, m_n\}$ and their spatial coordinates $\mathbf{x}$ over a period t . Then, the forward solution of the system can be written as

$$\mathbf{d} = g(\mathbf{x}, t, \mathbf{u}; \mathbf{m}) \quad (6)$$

where $\mathbf{d} = \{d_1, \dots, d_p\}$ is the response of the system.

Since interest is now focused on the parameters, Eq. 6 can be written for simplicity as

$$\mathbf{d} = g(\mathbf{m}) \quad (7)$$

As previously stated, the objective of the inverse problem

in geosciences is to estimate the spatiotemporal distribution of the parameters $\mathbf{m}$ by using all the available information such as physical laws, measurements and moments concerning the parameters, and also measurements of the response variables (e.g., head measurements). Under the probabilistic formalism, the response variable $\mathbf{d}$ and the parameter set of the system are considered as random variables. The vector of observations $\mathbf{d}_{\text{obs}}$ is considered as the response from a particular parameter set, which has to be determined. In order to define a statistical distribution for $\mathbf{d} | \mathbf{m}$, a known error distribution of the observations has to be assumed (likelihood of data). Also, it is important to consider a known distribution $f(\mathbf{m})$ of the parameters (prior knowledge). Then, according to Bayes's theorem, the a posteriori distribution of the parameters is defined as

$$f(\mathbf{m}|\mathbf{d}) = \frac{f(\mathbf{d}|\mathbf{m})f(\mathbf{m})}{f(\mathbf{d})} \quad (8)$$

where $f(\mathbf{d}|\mathbf{m})$ is the likelihood of data and $f(\mathbf{m})$ is the prior distribution of the parameter set (see derivation below). Repeating the calculation of Eq. 8 for different parameter sets derived from the prior distribution and producing different $\mathbf{d}_{\text{obs}}$ sets, we can obtain the a posteriori distribution of $\mathbf{m}$. Then, the best estimator of $\mathbf{m}$ is the one that maximizes the a posteriori probability $f(\mathbf{m} | \mathbf{d})$. This methodology is known as the maximum a posteriori probability (MAP) (Oliver et al. 2008).

Derivation

In its simple form for events as in Eq. 1, Bayes's theorem is derived from the definition of conditional probability:

$$P(\mathcal{A}|\mathcal{B}) = \frac{P(\mathcal{A} \cap \mathcal{B})}{P(\mathcal{B})}, \text{ with } P(\mathcal{B}) \neq 0 \text{ and}$$

$$P(\mathcal{B}|\mathcal{A}) = \frac{P(\mathcal{B} \cap \mathcal{A})}{P(\mathcal{A})}, \text{ with } P(\mathcal{A}) \neq 0$$

where $P(\mathcal{A} \cap \mathcal{B})$ is the joint probability of events $\mathcal{A}$ and $\mathcal{B}$.

$$\text{Since } P(\mathcal{A} \cap \mathcal{B}) = P(\mathcal{B} \cap \mathcal{A}) \Rightarrow P(\mathcal{A} \cap \mathcal{B}) = P(\mathcal{A}|\mathcal{B})P(\mathcal{B}) = P(\mathcal{B}|\mathcal{A})P(\mathcal{A})$$

$$\Rightarrow P(\mathcal{A}|\mathcal{B}) = \frac{P(\mathcal{B}|\mathcal{A})P(\mathcal{A})}{P(\mathcal{B})}, \text{ if } P(\mathcal{B}) \neq 0$$

In the continuous case of random variables as used in Eq. 8, the theorem can be derived in an analogous manner from the definition of conditional probability (Fig. 2):

Bayes's Theorem, Fig. 2 On the proof of continuous case of Bayes's theorem: Conditional probabilities applied to the event space of random variables X and Y . By equating these probabilities in the infinitesimal prism formed by the intersection of the two stripes, an instance of Bayes's theorem is revealed for each point in the domain. Integrating these instances for x and y , Eq. 9 is derived

$$P(Y=y|X=x) = \frac{P(X=x \cap Y=y)}{P(X=x)}$$

$$P(X=x|Y=y) = \frac{P(X=x \cap Y=y)}{P(Y=y)}$$

$$f_{X|Y=y}(x) = \frac{f_{X,Y}(x,y)}{f_Y(y)} \text{ and}$$

$$f_{Y|X=x}(y) = \frac{f_{X,Y}(x,y)}{f_X(x)}$$

Hence,

$$f_{X|Y=y}(x) = \frac{f_{Y|X=x}(y)f_X(x)}{f_Y(y)} \quad (9)$$

Bayesian Statistics

Stochastic methods in geosciences do not adopt in general the classic statistical but rather the Bayesian view, where probabilities represent states of knowledge or accessible information. The main point in this view is that the variable of interest over an area is modeled as a random function because there is inadequate information to enable the use a deterministic model, rather than due to the “law of large numbers,” that is, because repeated observations indicate a statistical regularity (Kitanidis 2007).

Thus, in Bayesian statistics, probability is used as a measure of uncertainty, or “belief,” or available information about an event. In the context of spatial estimation, which is of main concern in geosciences, the essence is to comply with two requirements: Include all previous knowledge about spatial variability in a highly informative prior distribution and then use the observations to infer a maximized posterior

distribution through Bayes's relation (Christakos 1990; Valakas and Modis 2016). Classical Kriging estimators can also derive under this generalized perspective: Since prior information is limited to the mean and covariance functions and only exact measurements are considered, maximization of entropy leads to Gaussian prior and posterior distributions. Then, the minimum mean squared error estimator equals the conditional mean according to Bayes's theorem (Christakos 2000).

Conclusions

Bayes's theorem relates events or random variables by avoiding using their joint probability in favor of conditional and marginal ones. In many cases, these probabilities are easier to define.

In mineral exploration, it provides the tools to update our knowledge on the subsurface with data from different sources of fuzzy information.

In geological modeling, Bayes's theorem is used to transform the prior distribution of the system's parameters into a narrower posterior distribution by using a set of uncertain measurements of the response variables.

Definition

Bayesian inversion is a statistical method used in many geoscience applications to assess the probability distribution of the unknown variables conditioned on the available measurements, where the posterior model is uniquely defined by a prior model representing the knowledge of the variable before the data acquisition and a likelihood model linking the target variables and the measured data.

Introduction

Geophysics theories, such as seismology, electromagnetism, and poro-elasticity, include mathematical relations of the physical processes and properties of rock and fluid properties in the subsurface. If the rock and fluid physical properties are

known, then it is possible to apply a forward operator to predict the geophysical response of the subsurface. For example, if the volumetric fractions of the mineral and fluid components of porous rocks are known, then their seismic response can be predicting by solving a set of poro-elastic equations. In practice, the petrophysical properties of the porous rocks are unknown, whereas their geophysical response can be measured using geophysical methods, such as seismic acquisition. Therefore, the prediction of the rock and fluid properties from geophysical measurements can be defined as an inverse problem. Bayesian methods are commonly used in geophysical inverse problems (Tarantola 2005).

Geophysical inverse problems are often ill-posed and the solution is generally nonunique. Bayesian inverse theory provides a mathematical framework for these problems since it aims at calculating the posterior probability distribution of the variables of interest conditioned on the measured data by combining the prior distribution of the model variables with the likelihood function of the data. The prior model represent the knowledge of the variables of interest prior to the data acquisition, whereas the likelihood model links the variables of interest and the measured data. The posterior model is then uniquely identified by these two models (Tarantola 2005). The posterior model can be computed analytically for certain classes of likelihood and prior models, but in the general case, the posterior distribution must be assessed numerically, by iteratively approximating the solution. Bayesian methods have been proposed for a variety of geophysical inverse problems (Mosegaard and Tarantola 1995; Scales and Tenorio 2001; Ulrych et al. 2001; Buland and Omre 2003; Tarantola 2005; Rimstad et al. 2012).

The focus of this entry is on seismic inverse problems for the prediction of subsurface properties from seismic measurements (Aki and Richards 1980). The geophysics literature includes a variety of formulations of the seismic inversion problem, which differ for the formulation and parameterization of the physical operator. Indeed, the seismic inverse problem can be formulated in terms of elastic properties (seismic velocity and density or seismic impedance) or petrophysical properties (porosity, mineral volumes, and fluid saturations), and the physics can include the full wave propagation model or linearized approximations. For linear formulations and under Gaussian assumptions, analytical solutions of the Bayesian inverse problem are derived (Buland and Omre 2003; Grana et al. 2017), whereas for nonlinear formulations, Monte Carlo methods must be adopted to approximate the posterior distribution (Mosegaard and Tarantola 1995; Sambridge and Mosegaard 2002).

In the following, we review the main principles of Bayesian inverse theory, present analytical solutions for linear inverse problems assuming Gaussian and Gaussian mixture

distributions, and present an overview of Markov chain Monte Carlo methods. These methods are illustrated on a one-dimensional synthetic seismic dataset for the prediction of the elastic properties of porous rocks in the subsurface.

Methods

In geophysical inverse problems, the variable of interest is a physical property in the subsurface, defined on a spatial grid, and it is represented here by the vector $\mathbf{m}$, whereas the geophysical data, such as seismic amplitudes, are represented here by the vector $\mathbf{d}$. The aim of the inverse problem is to assess the variables $\mathbf{m}$ given the measured data $\mathbf{d}$ associated with the forward model

$$\mathbf{d} = \mathbf{f}(\mathbf{m}) + \mathbf{e}, \quad (1)$$

where $\mathbf{f}(\cdot)$ is the geophysical forward operator and $\mathbf{e}$ represents the measurement errors. For example, the data can be seismic measurements and the model variables can be elastic and petrophysical properties of porous rocks. The forward operator $\mathbf{f}(\cdot)$ can be represented by linear or nonlinear physical relations.

In a deterministic setting, the least square solution $\hat{\mathbf{m}}$ can be obtained by minimizing the L2 norm of the residuals $\mathbf{r} = \mathbf{d} - \mathbf{f}(\mathbf{m})$, i.e., difference between measured and predicted data:

$$\hat{\mathbf{m}} = \arg \min_{\mathbf{m}} \|\mathbf{d} - \mathbf{f}(\mathbf{m})\|_2. \quad (2)$$

For ill-conditioned and rank-deficient systems, singular value decomposition or regularization methods, such as Tikhonov regularization, are generally applied.

In a probabilistic setting, the solution of the inverse problem is expressed as the posterior probability distribution $p(\mathbf{m}|\mathbf{d})$ of the variables given the measured data, which can be assessed using Bayes' theorem

$$p(\mathbf{m}|\mathbf{d}) = \frac{p(\mathbf{d}|\mathbf{m})p(\mathbf{m})}{p(\mathbf{d})} = \text{const} \times p(\mathbf{d}|\mathbf{m})p(\mathbf{m}) \quad (3)$$

where $p(\mathbf{m})$ is the prior distribution of the variables, $p(\mathbf{d}|\mathbf{m})$ is the data likelihood function, and $p(\mathbf{d})$ is a normalizing constant to guarantee that the posterior distribution $p(\mathbf{m}|\mathbf{d})$ is a valid probability distribution.

The Bayesian inversion concept is graphically displayed in Fig. 1. The goal is to assess the variable of interest $\mathbf{m}$ given a value $\mathbf{d}^0$ of the measured data $\mathbf{d}$. Figure 1a displays the likelihood model $p(\mathbf{d}|\mathbf{m})$ and the prior model $p(\mathbf{m})$. The Bayesian inversion operates in the $[\mathbf{m} \times \mathbf{d}]$ -space. The forward operator $\mathbf{f}(\mathbf{m})$ and the associated random error $\mathbf{e}$ define the likelihood model $p(\mathbf{d}|\mathbf{m})$, whereas the prior model $p(\mathbf{m})$ with prior expectation μ_m is specified based on the prior knowledge of the variable $\mathbf{m}$. Figure 1b displays the joint distribution $p(\mathbf{m}, \mathbf{d}) = p(\mathbf{d}|\mathbf{m})p(\mathbf{m})$ as a contour map. The joint model fully defines the interaction between $\mathbf{m}$ and $\mathbf{d}$. The marginal distribution $p(\mathbf{d})$ is obtained by integrating $p(\mathbf{m}, \mathbf{d})$ over the values of the variable $\mathbf{m}$. The normalizing constant $p(\mathbf{d}^0)$ is obtained by evaluating the marginal distribution in the data value $\mathbf{d}^0$.

Figure 1c displays the posterior distribution $p(\mathbf{m}|\mathbf{d}^0) = p(\mathbf{m}, \mathbf{d}^0)/p(\mathbf{d}^0)$ in Eq. 3 and its posterior expectation $\mu_{m|\mathbf{d}^0}$.

Bayesian Inversion in Geoscience, Fig. 1 Graphical representation of Bayesian inversion: (a) prior and likelihood models, (b) joint model, and (c) posterior model

$\mu_{m|d^0}$ for the data value d^0 . In the general case, the prior and posterior models might not be Gaussian. For highly skewed or multimodal distributions, the variable values associated with the maximum of the prior and posterior models are generally more informative than the prior and posterior expectations.

Bayesian Linear Inversion

In the case of linear operators, the forward model in Eq. 1 is rewritten as a linear system of equations

$$d = \mathbf{F}m + e, \quad (4)$$

where $\mathbf{F}$ is the matrix defined by the linear operator $f(\cdot)$. If the random error e is assumed to be Gaussian with $\mathbf{0}$ -mean and covariance matrix equal to Σ_e , then the likelihood model $p(d|m)$ is Gaussian

$$p(d|m) = \mathcal{N}(d; \mathbf{F}m, \Sigma_e) \quad (5)$$

with expectation $\mathbf{F}m$ linear in m and covariance matrix Σ_e .

If the prior model of the variables $p(m)$ is Gaussian, then the posterior model of the variables given the measured data $p(m|d)$ is also Gaussian. Hence, the prior and posterior models are conjugate distributions with respect to the likelihood model $p(d|m)$. For a Gaussian prior model $p(m) = \mathcal{N}(m; \mu_m, \Sigma_m)$ with expectation μ_m and covariance matrix Σ_m , the posterior distribution of the variable $[m|d]$ is also Gaussian

$$p(m|d) = \mathcal{N}(m; \mu_{m|d}, \Sigma_{m|d}) \quad (6)$$

with conditional expectation $\mu_{m|d}$ and conditional covariance matrix $\Sigma_{m|d}$ given by

$$\mu_{m|d} = \mu_m + \Sigma_m \mathbf{F}^T [\mathbf{F} \Sigma_m \mathbf{F}^T + \Sigma_e]^{-1} (d - \mathbf{F} \mu_m), \quad (7)$$

and

$$\Sigma_{m|d} = \Sigma_m - \Sigma_m \mathbf{F}^T [\mathbf{F} \Sigma_m \mathbf{F}^T + \Sigma_e]^{-1} \mathbf{F} \Sigma_m, \quad (8)$$

respectively. The posterior variances of the marginal distributions are independent of the measurement values and only depends on the parameters of prior model and measurement errors. The derivation can be found in Tarantola (2005).

In Buland and Omre (2003), the Bayesian linear formulation is applied to the seismic inversion problem. This approach is referred to as Bayesian linearized amplitude-versus-offset (AVO) inversion. The linear forward operator is obtained by assuming a convolution of a known wavelet and the linearized AVO approximation (Aki and Richards 1980) of the reflectivity coefficients that are function of the time-derivative of the logarithm of the elastic properties. The

convolution is a linear operator, hence the forward operator can be expressed by a matrix multiplication, $\mathbf{F} = \mathbf{WAD}$, where $\mathbf{W}$ is the wavelet matrix, $\mathbf{A}$ is the reflectivity coefficient matrix, and $\mathbf{D}$ is a first-order differential matrix. The forward operator is then linear with respect to the logarithm of the elastic properties $\ln(m)$ (where m is here a dimensionless representation of the parameters) and the linear expression in Eq. 4 can be written as $d = \mathbf{WAD} \ln(m) + e$. In Buland and Omre (2003), a Gaussian distribution for the logarithm of the elastic properties $\ln(m)$ is assumed, which entails a log-Gaussian prior model of the variable m . Based on these assumptions, the seismic inversion problem is analytically tractable and the posterior model of $[\ln(m)|d]$ is Gaussian, which entails a log-Gaussian posterior model of the variable $[m|d]$ (Buland and Omre 2003).

Gaussian mixture distributions are also conjugate models with respect to the likelihood function $p(d|m)$. If the prior model of the variables is a Gaussian mixture distribution $p(m) = \sum_k p(k) \mathcal{N}(m; \mu_{m|k}, \Sigma_{m|k})$, then the posterior model of the variables given the measured data is also a Gaussian mixture distribution

$$p(m|d) = \sum_k p(k|d) \mathcal{N}(m; \mu_{m|d,k}, \Sigma_{m|d,k}) \quad (9)$$

with conditional mean $\mu_{m|d,k}$ and conditional covariance matrix $\Sigma_{m|d,k}$, given by

$$\mu_{m|d,k} = \mu_{m|k} + \Sigma_{m|k} \mathbf{F}^T [\mathbf{F} \Sigma_{m|k} \mathbf{F}^T + \Sigma_e]^{-1} (d - \mathbf{F} \mu_{m|k}), \quad (10)$$

and

$$\Sigma_{m|d,k} = \Sigma_{m|k} - \Sigma_{m|k} \mathbf{F}^T [\mathbf{F} \Sigma_{m|k} \mathbf{F}^T + \Sigma_e]^{-1} \mathbf{F} \Sigma_{m|k}, \quad (11)$$

respectively (Grana et al. 2017). Due to the spatial coupling of the likelihood model in many geophysical applications, the posterior probability $p(k|d)$

$$p(k|d) = \frac{p(d|k)p(k)}{p(d)} = \text{const} \times p(d|k)p(k) \quad (12)$$

cannot be analytically computed. The numerical calculation of $p(k|d)$ is computationally demanding, hence it must be numerically approximated (Grana et al. 2017).

In the framework of Bayesian inverse theory, Monte Carlo methods can be used to generate realizations of the posterior distribution of Gaussian linear inverse problems, honoring a covariance function describing the spatial continuity of the variables.

Monte Carlo Methods

For general nonlinear problems in Eq. 1, analytical solutions are generally not available and numerical techniques such as Monte Carlo and Markov chain Monte Carlo (MCMC) algorithms must be adopted to approximate the posterior distribution (Mosegaard and Tarantola 1995; Sambridge and Mosegaard 2002). In Monte Carlo acceptance/rejection sampling approaches, the posterior distribution is approximated by sequentially drawing proposals from a prior distribution of the variable and accepting or rejecting the proposal based on its likelihood. In MCMC methods, the posterior distribution is approximated by sequentially drawing proposals from a proposal distribution conditioned on the previous realization of the variable.

Markov chain Monte Carlo methods design a random walk in the variable space using a Markov chain, i.e., a random process in which the probability of moving from the previous state to the current state is defined by a transition probability that depends only on the previous state. In applications to inverse problems, this process is used to draw realizations from the posterior distribution. The sequence of samples, i.e., the Markov chain, asymptotically reaches a stationary distribution that is equal to the posterior distribution of the Bayesian inverse problem. There are different Markov chain Monte

Carlo algorithms, including Metropolis, Metropolis-Hastings, and Gibbs sampling.

The most general MCMC technique is the Metropolis-Hastings algorithm. According to a Metropolis-Hastings approach frequently used in geoscience, an initial realization $\mathbf{m}_0$ is generated from the prior distribution $p(\mathbf{m})$ and represents the initial state of the chain. Then, at each iteration i , the proposed realization $\mathbf{m}_p$ is generated by sampling from a proposal distribution $g(\mathbf{m}|\mathbf{m}_{i-1})$ conditioned on the state $\mathbf{m}_{i-1}$ at the previous iteration. The proposed realization is accepted with probability

$$p^* = \min \left(\frac{p(\mathbf{d}|\mathbf{m}_p)p(\mathbf{m}_p)g(\mathbf{m}_{i-1}|\mathbf{m}_p)}{p(\mathbf{d}|\mathbf{m}_{i-1})p(\mathbf{m}_{i-1})g(\mathbf{m}_p|\mathbf{m}_{i-1})}, 1 \right) \quad (13)$$

If accepted, the proposed realization is assigned to the current state $\mathbf{m}_i = \mathbf{m}_p$, otherwise $\mathbf{m}_i = \mathbf{m}_{i-1}$. The MCMC algorithm converges in the sense that the generated states represent realizations from the posterior model, as iterations increase. The Gibbs sampling is a special case of the Metropolis-Hastings algorithm, and it generates proposals from the full conditional distribution of subdimensions of $\mathbf{m}_i$, hence $p^* = 1$ in Eq. 14, such that the proposed state is

Bayesian Inversion in

Geoscience, Fig. 2 Synthetic seismograms representing the seismic measurements: from left to right, seismograms for incident angles of 12°, 24°, and 36°

always accepted. However, in many applications, this advantage of the Gibbs sampler is offset by the need to compute full conditional distributions at each iteration.

In the Metropolis approach, the proposal distribution $g(\mathbf{m}|\mathbf{m}_{i-1})$ is assumed to be symmetric, such that $g(\mathbf{m}|\mathbf{m}_{i-1}) = g(\mathbf{m}_{i-1}|\mathbf{m})$ and the acceptance probability becomes

$$p^* = \min\left(\frac{p(\mathbf{d}|\mathbf{m}_i)p(\mathbf{m}_i)}{p(\mathbf{d}|\mathbf{m}_{i-1})p(\mathbf{m}_{i-1})}, 1\right) \quad (14)$$

Monte Carlo and Markov chain Monte Carlo approaches are adopted for seismic and petrophysical inversion problems and combined with analytical approximations to sample from the posterior distributions. The methodology is used for litho-fluid classification (Grana et al. 2017) and is also extended to seismic classification problems including categorical variables (de Figueiredo et al. 2019).

Example

We illustrate the application of Bayesian inverse methods to a seismic inversion problem to predict the elastic properties

along a one-dimensional profile from a set of seismograms measured with different acquisition geometries. The subsurface variables of interest are: P-wave velocity, S-wave velocity, and density. The measured data include three synthetic seismograms computed from a set of borehole data for incident angles of 12° , 24° , and 36° (Fig. 2). The forward operator is a convolution of a known wavelet and the reflectivity coefficients computed from the elastic properties, according to Aki-Richards approximation for the linearized operator and according to Zoeppritz equations for the nonlinear operator (Aki and Richards 1980).

First, we apply the Bayesian linearized AVO inversion proposed in Buland and Omre (2003) to the seismic dataset in Fig. 3 by using the Aki Richards approximation. The prior distribution model is a trivariate Gaussian distribution of the logarithms of the elastic properties. The prior mean is represented by a low frequency trend of the elastic properties computed by filtering the well log data at a cutoff frequency equal to the lower bound of the seismic bandwidth. The prior covariance matrix is estimated from the difference between the actual well measurements and the prior mean. The prior model includes an exponential spatial correlation function with correlation length of 20 ms. The marginal distributions

Bayesian Inversion in Geoscience, Fig. 3 Prior distribution of the model variables: from left to right, P-wave velocity, S-wave velocity, and density. Solid black lines represent the true model, dashed black lines represent the mean, and dotted black lines represent the 0.90 confidence interval

of the prior model are shown in Fig. 3. The measurement error is assumed to be spatially uncorrelated with 0-mean and variance equal to 20% of the variance of the data, corresponding to a signal-to-noise ratio of 5. The posterior distribution of the elastic variables is then the Gaussian distribution of the logarithms of the elastic properties defined in Eq. 6 with parameters given by the analytical expressions in Eqs. 7 and 8. The marginal components of the posterior distribution of the elastic variables are shown in Fig. 4. The maximum posterior predictions of the marginal distribution are in good agreement with the reference data.

We also apply a Markov chain Monte Carlo method based on the Metropolis-Hastings algorithm to the same seismic dataset using the convolutional operator and the nonlinear Zoeppritz equations. The prior realization of the model variables is generated by sampling from the trivariate prior distribution with exponential spatial correlation function used in the previous example. The proposal distribution is assumed to be Gaussian. In this application, 4000 proposals are drawn from the proposal distribution with an acceptance rate of approximately 24%. Figure 5 shows 500 realizations randomly selected after convergence. The algorithm is repeated

10 times, starting from different states, to avoid that results might be biased by the initial realization of the chain.

Conclusions

Bayesian inversion methodologies are commonly adopted in geophysical inverse problems for the assessment of the posterior distribution of the subsurface variables conditioned on the available data. The Bayesian approach provides a natural framework to predict the most likely solution and to quantify the associated uncertainty. For linear inverse problems, with Gaussian prior distribution and linear likelihood operators with additive Gaussian errors, the posterior distribution is also Gaussian and the posterior mean and covariance matrix can be analytically assessed. The analytical tractability makes the approach very efficient and easily extendable to three-dimensional studies. For nonlinear problems, the posterior distribution is iteratively approximated using stochastic simulation algorithms such as the Markov chain Monte Carlo method. The need for iterative algorithms makes the approach computationally demanding, especially for large datasets. A demonstration of the two approaches is presented on a

seismic inversion problem assessing the posterior distribution of elastic properties of subsurface porous rocks. The Bayesian approach can be extended to other model parameterizations and formulations, to include rock physics models for the prediction of petrophysical properties. Furthermore, categorical variables associated with geological concepts can be included for the classification of litho-fluid classes. Such formulations generally require more complex prior models, combining Gaussian mixture distributions with Markov random fields.

Definition

The Bayesian maximum entropy (BME) theory of spatiotemporal geostatistics is concerned with the modeling and

estimation/mapping of natural attributes (such as physical variables, ecologic processes, health parameters, and social indicators varying in the chronotopologic domain) in a chronotopologic domain (both the space-time and the spacetime are considered here). BME has introduced significant advances in the field of spatiotemporal geostatistics including an improved knowledge-theoretic modeling framework under condition of in situ uncertainty that is free of the restrictive assumptions of classical geostatistics (normality, linearity etc.); it can integrate a variety of core-general and case-specific knowledge bases (including physical laws, scientific theories, theoretical models, empirical evidence, soft data, and auxiliary information).

Introduction

The introduction of *Bayesian maximum entropy* (BME; Christakos 1990) provided a new way to address some shortcomings of previous notions and techniques (e.g., purely spatial considerations, spatial statistical regression) by means of a more broadly designed epistemic framework for geostatistical analysis and mapping. For example, Kriging, a linear estimator, is a statistical error minimization technique that relies on the Gaussian assumption; it focuses on low-order moments, and it cannot process important types of uncertain information and core knowledge (Olea 1999). BME is a knowledge-based approach, which, based on a theoretical support of considerable generality, can integrate the content of different information sources to achieve a realistic representation of natural phenomena which generate predictions of improved accuracy (Christakos and Serre 2000; Lee et al. 2008). BME provides the foundations to integrate knowledge bases of various kinds, both site-specific bases (such as additional ground measurements, satellite observations, and empirical charts) and core bases (including physical laws, basic principles, and theoretical models) (Kolovos et al. 2012). This is a particularly attractive feature in contemporary data-driven analytical environments, because BME enables the generation and integration of valuable information from core knowledge bases that might be otherwise left unused (Kolovos et al. 2002). Most prominently, BME extends one's ability to use measured data beyond single-value observations (Christakos and Li 1998; Christakos 2000). Specifically with respect to uncertainty, BME discriminates between two types of data, namely, the hard data and the soft data. Data whose observations are considered to be exact in the scope of an analysis are termed hard data. In contrast, soft data represent observed data that might carry nontrivial uncertainty in the context of a study. For example, soft data can be the result of routine sources of uncertainty such as the inaccuracy of measuring devices, modeling uncertainties, and human error. Alternatively, soft data can be derived as a result of

inadequate knowledge, revised assessments, intuition estimates, and a host of other similar mechanisms that may provide uncertain informative content (Kolovos et al. 2016). BME is also free of additional limitations and restrictions that burden other geostatistical methods; for example, the BME analysis is independent of the data distribution (e.g., non-Gaussian distributions can be automatically incorporated), whereas Kriging is unable to accurately handle heavy tailed data (Christakos et al. 2001). In addition, the BME theoretical foundation enables both univariate and multivariate predictions (Hristopulos and Christakos 2001). Per the detailed method comparison in Christakos (2000), in the course of the decades since its introduction, BME has been providing equally or more accurate prediction patterns than Kriging (e.g., Lee et al. 2008; Bogaert et al. 2009; Lee et al. 2010; Christakos 2010; Li et al. 2013c; Gao et al. 2014; Shi et al. 2015a).

Since its inception, BME has demonstrated its robust ability for spatiotemporal data analysis and modeling through a wide spectrum of applications in Earth and environmental sciences, public health, ecology, remote sensing, energy, resources science, and real estate research. A sample of the relevant literature includes Christakos et al. (2004), Heywood et al. (2006), Law et al. (2006), Brus et al. (2008), Savelieva et al. (2010), Kolovos et al. (2010), Yu et al. (2011), Angulo et al. (2013), Li et al. (2013a, b), Shi et al. (2015b), Sun et al. (2015), Yang and Christakos (2015), Zagouras et al. (2015), Hu et al. (2016), Tang et al. (2016), Kou et al. (2016), Hayunga and Kolovos (2016), He et al. (2019a), Zhang and Yang (2019a, b), and Wei et al. (2020). The BME methodology will be briefly reviewed next.

BME Methodology

The Knowledge Bases (KB)

At the beginning of BME (and of any scientific inquiry, as a matter of fact), knowledge bases is the available *knowledge* about the phenomenon of interest. Broadly speaking, the knowledge considered in real-world applications comes from a variety of sources, including all kinds of valid information available at a given moment and obtained by the competent scientist using effectively a scientific procedure. BME distinguishes between two major *knowledge bases* (KB):

- (i) *Core or general G-KB*, which is background knowledge and justified beliefs relative to the phenomenon of interest. The *G* may include physical laws, scientific theories and models, structured patterns and assumptions, analytic and synthetic statements, and previous experience with similar phenomena independent of any case-specific data.

- (ii) *Site-specific* or *specificatory* *S*-KB, which is targeted knowledge about the specific situation that may include both external or demonstrative evidence (actual measurements, perceptual or data of sense, etc.) and internal or inductive evidence (inferring one thing from another thing, empirical propositions, expertise with similar situations).

The synthesis of the *G*-KB and the *S*-KB provides the *total* KB. More specifically, the *G*-KB is expressed in terms of a series of suitable functions g_α of the attribute realization χ_{map} at the point set $\mathbf{p}_{map}$ of interest, i.e., $g_\alpha(\chi_{map})$, $\alpha = 0, 1, \dots, N_c$ (by convention $g_0 = 1$). The g_α -functions account for a variety of core knowledge sources including statistical moments, empirical relationships, and physical laws. There are two conditions that guide the choice of the g_α -functions: (a) their stochastic expectations $\bar{g}_\alpha = \int d\chi_{map} g_\alpha f_G$ must be calculable at the point set $\mathbf{p}_{map}$ (which includes the sampled points and any unsampled points of interest), where f_G is a probability density function (PDF) constructed on the basis of the *G*-KB, and (b) the resulting equations must be solvable with respect to the unknown parameters of the g_α functions (these parameters are functions of $\mathbf{p}_{map}$). Examples of *G*-KB formulated in terms of the g_α -functions include (Christakos 2000; Wu et al. 2021) $\int d\chi_{map} g_\alpha O_\alpha[f_G] = 0$, where the g_α have forms associated with algebraic or differential operators O_α with respect to f_G (which includes derivatives of the attribute PDF with respect to the coordinates).

For practical purposes, the following *S*-KB distinction is usually adopted by BME: (a) *hard* data χ_h , which is the *S*-KB obtained from real-time observation devices with the probability of the attribute value in each datum being 1 (which is why it is also called *certain* data), and (b) *soft* data χ_s , which is the *S*-KB that includes non-negligible uncertainty (imprecision or vagueness) and is stochastically expressed as $\int d\Phi(\chi_s) f_S(\Phi) \in [0, 1]$, where f_S is a PDF constructed on the basis of the available *S*-KB and Φ and I are a specified empirical model (a wide variety of choices, depending on the real-world application) and interval of values, respectively (Wu et al. 2021).

Compared to the mainstream geostatistical approaches, BME not only follows a data-driven workflow but also considers general knowledge to describe a natural process or phenomena, including physical laws, basic principles, scientific theories, etc. In this sense, BME is a *theory-based data-driven* approach. Using this kind of knowledge may steer easier or more precise chronotopologic data analysis in the following cases: (i) an inadequate number of data might be available for conclusive analysis, and (ii) uncertainty in data can bias results and might even lead to flawed analyses if unacknowledged.

The Chronotopologic Domain

A *chronotopologic domain* is a term used to describe either a space-time domain (i.e., space and time are considered separately) or a spacetime domain (i.e., space and time are considered as an integrated whole). Chronotopologic domain points are denoted by the vector $\mathbf{p}$, which includes both spatial and temporal coordinates. In Table 1, a distinction is presented between sets of points $\mathbf{p}$ within the chronotopologic domain.

The Spatiotemporal Random Field Model

The *spatiotemporal random field* theory (STRF, Christakos 1991, 2017) studies natural attributes and phenomena that evolve in the chronotopologic continuum. An S/TRF $X(\mathbf{p})$ is a collection of complementary field realizations associated with the values of an attribute field at points of the chronotopologic domain, where the j^{th} -realization at $\mathbf{p}_{map}$ is written as $\chi_{map}^{(j)} = [\chi_{d1}^{(j)} \dots \chi_{dn_d}^{(j)} \chi_{k1}^{(j)} \dots \chi_{kn_k}^{(j)}]^T$ ($j = 1, 2, \dots$). In light of the notation in Table 1, it is commonly written that $\chi_{map} = [\chi_d \chi_k]$, where $\chi_{data} = [\chi_{d1} \dots \chi_{dn_d}]^T$ denotes attribute measurements or observations at points $\mathbf{p}_i$ and $\chi_k = [\chi_{k1} \dots \chi_{kn_k}]^T$ denotes the unknown attribute values at points $\mathbf{p}_k$ ($k \neq i$).

In stochastic terms, $X(\mathbf{p})$ is fully described by the infinite sequence of probability density functions (PDF) $f_X(\chi_{map})$ covering all domain points. The mean S/TRF function $\bar{X}(\mathbf{p})$ represents trends and systematic structures that exist in a larger scale, the covariance function $c_X(\mathbf{p}, \Delta\mathbf{p}) = [\bar{X}(\mathbf{p}) - \bar{X}(\mathbf{p})][\bar{X}(\mathbf{p} + \Delta\mathbf{p}) - \bar{X}(\mathbf{p} + \Delta\mathbf{p})]$ describes chronotopologic dependencies between pairs of points $\mathbf{p}$ and $\mathbf{p} + \Delta\mathbf{p}$, and the trivariogram function $\zeta_X(\mathbf{p}, \Delta\mathbf{p}, \Delta\mathbf{p}') = [\bar{X}(\mathbf{p}) - \bar{X}(\mathbf{p})][\bar{X}(\mathbf{p} + \Delta\mathbf{p}) - \bar{X}(\mathbf{p} + \Delta\mathbf{p})][\bar{X}(\mathbf{p} + \Delta\mathbf{p}') - \bar{X}(\mathbf{p} + \Delta\mathbf{p}')] describes chronotopologic$

Bayesian Maximum Entropy, Table 1 Chronotopologic point sets to be considered in BME

<i>Entire point set</i>	Vector $\mathbf{p}_{map} = [\mathbf{p}_1 \dots \mathbf{p}_n]^T$, which includes the nodes of the chronotopologic mapping grid that covers the entire domain of interest
<i>Hard data point subset</i>	Vector $\mathbf{p}_h = [\mathbf{p}_{h1} \dots \mathbf{p}_{hn_h}]^T \subset \mathbf{p}_{map}$, which includes the points where exact data is available
<i>Soft data point subset</i>	Vector $\mathbf{p}_s = [\mathbf{p}_{s1} \dots \mathbf{p}_{sn_s}]^T \subset \mathbf{p}_{map}$, which includes the points where uncertain data is available
<i>Data point subset</i>	Vector $\mathbf{p}_d = [\mathbf{p}_{d1} \dots \mathbf{p}_{dn_d}]^T \subset \mathbf{p}_h \cup \mathbf{p}_s$, i.e., the union of $\mathbf{p}_h$ and $\mathbf{p}_s$.
<i>Unsampled point subset</i>	Vector $\mathbf{p}_k = [\mathbf{p}_{k1} \dots \mathbf{p}_{kn_k}]^T$, where no empirical evidence exists but attribute estimates (interpolations, extrapolations, predictions) are sought
<i>Point subset link</i>	Relationship holds between the set and the two main point subsets leading to the entire point set: $\mathbf{p}_{map} = \mathbf{p}_d \cup \mathbf{p}_k$.

Bayesian Maximum Entropy,
Fig. 1 Workflow of the BME
analysis

dependencies between triplets of points p , $p + \Delta p$, and $p + \Delta p'$, where Δp and $\Delta p'$ are chronotopologic lags.

The BME Workflow

The basic BME stages are outlined in Fig. 1. Table 2 describes the BME methodology in terms of the g_a ($a = 1, \dots, N_c$) and Φ functions and the PDF f_G and f_S .

In more words, at the prior (*G-based*) stage, there is an inverse relation between prior information and prior probability: the more vague and general a theory is, the more alternatives it includes (and it is, hence, more probable) but also the less informative it is. In BME, maximization of information input serves as acquiring prior knowledge that can be filtrated, integrated, and optimized by specified rules and is a pivotal step to describe general attribute characteristics.

Thus, the prior PDF (*G-based*) f_G is defined by the calculated μ_a and the selected g_a , i.e., $f_G(\chi_{map}) = e^{\sum_{a=1}^{N_c} \mu_a g_a}$. The Lagrange multipliers μ_a ($a = 1, \dots, N_c$) calculated in the prior stage by information maximization quantify the significance of each g_a -function, whereas the μ_0 is a normalization parameter. The μ_a are themselves functions of p_{map} . Ideally, the more detailed G is, the thinner f_G becomes by excluding irrelevant outcomes, hence leading to a more informative model. Examples of the $(g_a, \bar{g}_a)$ pairs include theoretical models of the attribute mean, covariance, variogram, tri-variogram, higher-order chronotopologic moments, and equations expressing physical laws.

At the metaprior (*S-based*) stage, the *S-KB* is collected and organized in appropriate quantitative forms that can be explicitly incorporated into the BME formalism. This includes data cleaning, transformations, and evaluation, identification, and discrimination into hard and soft data, as appropriate for the analysis. Commonly encountered soft data forms are listed in Table 3.

In particular, the interval case in Table 3 shows that interval data values χ_i lie within a known interval I_i with lower and upper limits l_i and u_i , respectively; the probabilistic 1 case displays probabilistic data for which the cumulative distribution functions (CDF) $F_S(\zeta_i)$ are known; the probabilistic 2 case refers to threshold soft data, where the probabilities ϑ_i for certain

Bayesian Maximum Entropy, Table 2 Main BME stages

Stage	Formulation
Prior (<i>G-based</i>)	$\max_{\mu_a} \left[\text{Info}_G(\chi_{map}) = -\log e^{\sum_{a=1}^{N_c} \mu_a g_a} \right]$ $\text{s.t.} \int d\chi_{map} g_a e^{\sum_{a=1}^{N_c} \mu_a g_a} = \bar{g}_a$
Metaprior (<i>S-based</i>)	$\chi_d = \{\chi_h, \chi_s\}, \Phi, f_S$
Posterior (<i>K-based</i>)	$f_K(\chi_k) = \frac{1}{\int d\Phi f_S(\Phi) f_G(\chi_h, \Phi)} \int d\Phi f_S(\Phi) f_G(\chi_{map})$

Bayesian Maximum Entropy, Table 3 Examples of soft data formulations

Type of S-KB	Formulation $\chi_s = [\chi_{s1} \cdots \chi_{sn_s}]^T$ ($i = 1, \dots, n_s$)
Interval	$\chi_{si} \in I_i = [l_i, u_i]$
Probabilistic 1	$P_S[\chi_i \leq \zeta_i] = F_S(\zeta_i)$
Probabilistic 2	$P_S[\chi_i \in I_i] = \vartheta_i$
Functional	$P_S[h(\chi_i) \leq \zeta_i] = F_S(\zeta_i, h)$

threshold values I_i are known, and the functional case displays soft data, where the values can be derived from a given function h .

The posterior (*K-based*) stage is a synthesis stage in which the posterior probability is related to the *G-based* probability by means of a conditional probability knowledge-processing rule that draws inferences consistent with the available knowledge body and scientific reasoning. The *physical Bayesian conditionalization* rule is applied into the prior PDF f_G to produce the posterior PDF f_K and bring the model description closer to natural truth. According to the BME perspective, the *G-KB* introduces scientific consistency into the *S-KB*, and the *S-KB* introduces empirical conditioning into *G-KB* in light of the specific site considered. Interestingly, the above conclusion may be linked to the verifiability criterion used in sciences to constrain theoretical constructions by means of empirical evidence. With regard to material object claims, this criterion is known as “phenomenalism,” and with regard to the theoretical claims of science, as “operationalism.” Some examples of formulations corresponding to the interval, probabilistic, and functional soft data are presented

Bayesian Maximum Entropy, Table 4 Examples of posterior PDF formulations

Type of S-KB	Formulation $f_K(\chi_k)$
Interval	$\frac{1}{\int_{I_S} d\chi_S f_G(\chi_d)} \int_{I_S} d\chi_S f_G(\chi_k, \chi_d)$
Probabilistic 1	$\frac{1}{\int_{I_S} dF_G(\chi_s) f_G(\chi_d)} \int_{I_S} dF_G(\chi_s) f_G(\chi_k, \chi_s)$
Functional	$\frac{1}{\int_R dF_G(\zeta, h) \int_{I(\zeta)} d\chi_d f_G(\chi_d)} \int_R dF_G(\zeta, h) \int_{I(\zeta)} d\chi_S f_G(\chi_k, \chi_d)$

in Table 4, where I , R , and $I(\zeta)$ are definition domains that depend on the soft data.

BME Chronotopologic Estimation and Uncertainty Assessment

The obtained BME posterior PDF $f_K(\chi_k)$ at points $\mathbf{p}_k$ provides complete statistical description of the estimated (interpolated, extrapolated, predicted) attribute. In particular, the BME mode estimate $\hat{\chi}_{k,mode}$ is such that

$$f_K(\hat{\chi}_{k,mode}) = \max_{\chi_k} f_K(\chi_k);$$

the BME mean estimate $\hat{\chi}_{k,mean}$ is given by

$$\hat{\chi}_{k,mean} = \overline{X(\mathbf{p}_k)|\chi_d} = \int d\chi_k f_K(\chi_k) \chi_k;$$

and the BME median estimate $\hat{\chi}_{k,med}$ is defined as

$$\hat{\chi}_{k,med} = F_G^{-1}(0.5, \mathbf{p}_k) : \int_{\chi_k \leq \hat{\chi}_{k,med}} d\chi_k f_K(\chi_k) = \frac{1}{2}.$$

The determination of chronotopologic BME estimation uncertainty depends on the shape of the posterior PDF (symmetric vs. asymmetric, single maximum vs. multiple maxima, etc.; Wu et al. 2021). In particular, in the case of a symmetric attribute PDF, the estimation error variance is

$$e_X^2(\mathbf{p}_k) = \left[\overline{X(\mathbf{p}_k)} - \hat{X}(\mathbf{p}_k) \right]^2 = \int d\chi_k (\chi_k - \hat{\chi}_{k,mean})^2 f_K(\chi_k),$$

which is a widely used formula.

Interestingly, consider the special case where the following conditions are met concurrently: (i) the G -KB comprises only the attribute mean trend and covariance, that is, the first two stochastic moments of the attribute, and (ii) the S -KB contains only hard data. In this case, the BME equations reduce to Kriging, thus rendering Kriging a special case of chronotopologic BME estimation. In particular, the BME posterior PDF f_K is then fully defined by its mean and variance, and these measures correspond exactly to the Kriging prediction and prediction error, respectively.

BME Features and Applications

BME Versatility

Due to *BME*'s versatility, its basic equations possess significant generalization power on the basis of theory and data. As a consequence, the following essential *BME* features are of considerable interest as follows (Christakos 1998, 2000):

- (i) Well-known statistical interpolation techniques are derived as *special cases* of the chronotopologic BME theory. In the case, e.g., where the knowledge conditions $G = \{\bar{X}(\mathbf{p}), c_X(\mathbf{p}, \Delta\mathbf{p})\}$ and $S = \chi_h$ are met concurrently, the BME equations reduce to those of Kriging, thus rendering Kriging a special case of BME estimation (f_K is then determined by its mean and variance, which correspond to the Kriging estimation and estimation error variance, respectively).
- (ii) *BME* is a *nonlinear* chronotopologic estimator, in general.
- (iii) It incorporates *multi-sourced* knowledge bases (core and site-specific).
- (iv) It can process *higher-order* chronotopologic statistics associated with *non-Gaussian* data distributions, like skewness and kurtosis functions.
- (v) It has *extrapolation* (or *prediction*) abilities due to its incorporation of physical laws and other forms of core knowledge.
- (vi) It handles *functional*, *vector*, and *multipoint* chronotopologic estimation.
- (vii) It is *computationally* efficient, particularly in estimation cases where closed-form analytical expressions are available.

BME borrows strength from the Bayes rule and information theory, making it a versatile approach. On the one hand, the maximum entropy rule enables filtering out redundant knowledge and having useful knowledge left, which can also lead to more realistic chronotopologic estimations, and, on the other hand, the Bayes rule allows us to bring prior information (including not only statistical characteristic of the studied attribute but also physical laws, expert judgment, life experience, and skills) into considerations, which may save time/costs and lead to precise inference, even in the case that entire lack of data (Shoemaker et al. 1999; Christakos and Hristopulos 1998; Serre and Christakos 2002; Kolovos et al. 2002; McCarthy and Masters 2005; Kuhnert et al. 2010; Choy et al. 2009; Martin et al. 2012; Lang and Christakos 2019).

Another strength of the BME framework is the rigorous handling of soft data, i.e., uncertain data, such as historical records, secondary information, expert opinions, and beliefs. Therefore, BME can make maximal use of multi-sourced data and also provides a port to combine various mathematical

models (Money et al. 2011; Hu et al. 2016; Li et al. 2013a; Reyes and Serre 2014; He and Christakos 2018). This can significantly broaden the BME application range. Sometimes, soft data can be created by simple statistical methods for making up missing data in a time series case (Bayat et al. 2013; Lee et al. 2008). In other cases, the observed data may be vague, so sourcing expert advice, empirical handling of similar situations, intuition, and professional knowledge can be used to construct soft data (Serre et al. 2003; Puangthongthub et al. 2007; Yu and Wang 2013). Notice that compared to estimation without soft data, many studies have shown that including soft data can generate more accurate estimations (Christakos et al. 2001; D'Or et al. 2001; Shi et al. 2015b; Hayunga and Kolovos 2016).

The Emergence of Stochastic Logic in Geostatistics

The vast majority of the phenomena encountered in nature obey physical laws, which, in the case of classical physics, can be described in terms amenable to efficient *material causation* of logic theory. This is why BME's structure allows it to formally incorporate physical laws in a systematic and internally consistent manner. Mathematical logic is used because of the underlying deductive reasoning (if the premises are true, the conclusions are always true); on the other hand, when statistical inference is used (e.g., in statistical regression), because of the underlying inductive reasoning, the premises may be true and the conclusions wrong. Accordingly, BME has been extended in a stochastic logic context (Christakos 2002).

Indeed, beyond the conditional probability $P_G[\chi_k|\chi_d]$ used in the posterior stage of the original BME approach, other useful knowledge updating mechanisms can be expressed as the probability of *logical conditionals*, like the implication probability $P_G[\chi_d \rightarrow \chi_k]$, and the equivalence probability $P_G[\chi_d \leftrightarrow \chi_k]$, which are probabilistic expressions of the platitude that valid arguments are necessarily truth preserving. Otherwise said, these stochastic logic conditionals reveal that the relation of probability and deducibility involves the body of knowledge one actually has or the premises one actually accepts. Despite their conceptual differences, the above posterior probabilities are formally linked. For example, the standard (statistical) conditional probability is directly related to the implication probability as.

$[P_G[\chi_k|\chi_d] - 1]P_G[\chi_d] = P_G[\chi_d \rightarrow \chi_k] - 1$. Concluding, stochastic logic becomes a promising research avenue, when one realizes that the Bayes rule and the standard (statistical) conditional probability is not the only way to derive a posterior mapping probability in geostatistics.

BME in Software

There are several software libraries that can implement the BME theoretical developments, including the following: (i) BME library (BMELib) (Christakos et al. 2002), (ii) the

Spatiotemporal Epistemic Knowledge Synthesis Graphical User Interface (SEKS-GUI) (Yu et al. 2007), and (iii) the Space-Time Analysis Rendering with BME (STAR-BME) (Yu et al. 2012, 2016). The first two tools are Matlab-based compilations, while the third one was developed on Python. Each tool features a guided analysis through a sequence of screens across the different analysis tasks that start at importing data and extend all the way to visualization or results and exporting the analysis output.

Applications of BME in the Real World

Let us recall the basic function of BME approach, i.e., use known knowledge to explore the unknown natural process in space-time domain. Therefore, BME can be applied in a variety of disciplines (He and Kolovos 2018), as follows:

- The chronotopologic distribution of PM_{2.5}, ozone, NO_x concentrations, etc., was characterized and mapped for studying the human expose purpose by using BME or its combinations with land use regression models in the field of atmosphere (Christakos and Kolovos 1999; Bogaert et al. 2009; Nol et al. 2010; Yu and Wang 2010; Beckerman et al. 2013; Reyes and Serre 2014; Adam-Poupart et al. 2014; He and Christakos 2018; He et al. 2019a).
- For the lithosphere, BME was employed to study the heavy metal concentrations, electrical conductivity, moisture, organic matter in soil, and soil categories (D'Or and Bogaert 2003; Douaik et al. 2005; Brus et al. 2008; Modis et al. 2013; Gao et al. 2014; Sun et al. 2015).
- For the ecosphere, BME not only can study the natural beings (such as mercury concentration in fish tissue, young cork oak plantation, leaf area index, pedestrian mortality rates, etc., Money et al. 2011; Sedda et al. 2011; Li et al. 2013a; Fox et al. 2015) but also can depict the transmission and S/ST characteristics of a disease (such as black death, influenza, hand-foot-mouth, dengue fever, syphilis, hemorrhagic fever with renal syndrome, etc., Christakos et al. 2005; Law et al. 2006; Choi et al. 2008; Cao et al. 2010; Angulo et al. 2013; Yu et al. 2014; He et al. 2017, 2018, 2019b).
- Regarding the hydrosphere, groundwater contamination, level, and hydraulic conductivity were investigated by BME (Vyas et al. 2004; Messier et al. 2012, 2014, 2015; Yu and Chu 2010). Similarly, the inland water (such as the fecal contamination) was also characterized through BME (Coulliette et al. 2009; Money et al. 2009). Besides, the evolution of precipitation was studied in different areas with BME (Mahbub et al. 2010; Bayat et al. 2014; Zhang et al. 2016). With the largest area on the Earth, the oceans play a vital role in our planet's environmental cycle. Although the BME studies on oceans are not as much as on the other part of the Earth, but it has great potential to

show its versatile ability using the satellite remote sensing data on data fusion, spatiotemporal mapping, etc., see Li et al. (2013b), Tang et al. (2015), Shi et al. (2015b), and He et al. (2020a, 2020b).

Conclusions

BME provides a set of powerful tools supported by a rigorous theoretical framework, which are used to represent, estimate, and map natural attributes at unsampled locations under conditions of in situ uncertainty. BME displays a number of compelling characteristics on both theoretical and practical grounds, which make it stand out among mainstream geostatistics methods. On the theoretical front, BME makes no restrictive assumptions when it comes to properties like normality, linearity, and content-independency and is capable of ingesting information beyond the commonly used low-order moments and hard data. On the practical front, BME is built with the ability to integrate a variety of knowledge bases, including core knowledge bases (such as physical laws, theoretical models, and expert knowledge) and site-specific knowledge bases (such as empirical evidence, hard data, soft data, and secondary information).

Acknowledgement We would like to thank Dr. Alexander Kolovos for his valuable input to this work.

Best Linear Unbiased Estimation

Peter K. Kitanidis

Stanford University, Civil and Environmental Engineering & Computational and Mathematical Engineering, Stanford, CA, USA

Definition

Best linear unbiased estimation (BLUE) is a widely used data analysis and estimation methodology. Earth scientists and engineers are acquainted with this methodology in solving interpolation problems, *e.g.*, using Kriging, and data assimilation, using the ensemble Kalman filter (EnKF). Although based on probabilistic concepts, the method uses only the first two moments of probability distributions, *i.e.*, mean values and variances and covariances. Estimators are linear functions of data so the expected value of the error vanishes and the expected value of squared error is as small as possible.

Introduction

In the 1960s, pioneering works (Kalman 1960; Matheron 1963; Gandin 1965) introduced BLUE methods into applications. The objective in this chapter is to summarize the key ideas and equations of this methodology.

To fix ideas, assume we have measured a quantity z , such as temperature that varies with spatial coordinate x , at a number of locations, $x_1, x_2, \dots, x_n$. The measured quantities $z_1, z_2, \dots, z_n$ constitute our *data*. Our objective is to *estimate* the value of z at intermediate locations x . There are many ways to obtain a value of z at x from the data. The vast majority of them compute a value $\hat{z}(x)$ using linear operations. For example, for $x_1 < x < x_2$, $\hat{z}(x) = \lambda_1 z_1 + \lambda_2 z_2$, where $\lambda_1 = \frac{x_2 - x}{x_2 - x_1}$, $\lambda_2 = \frac{x - x_1}{x_2 - x_1}$. The estimated function consists of straight linear segments between successive data points. By

choosing more points and different weights, one can estimate a function that is smooth, meaning it has continuous first derivatives. One may also utilize weighting schemes in which the estimate reproduces the observations only approximately in favor of more uniformity.

One issue is to select a weighting scheme that is more accurate. Another issue is to quantify the estimation uncertainty, *i.e.*, evaluate in an average sense how close the estimate may be to the true value. Both issues are challenging. Best linear unbiased estimation (BLUE) is a statistical methodology to address these issues in a systematic and logical way. The hallmark of this approach is practicality, with low informational and computational requirements. Significantly, the method uses only the first two moments of probability distributions, *i.e.*, mean values and variances and covariances. The main features of the methodology are:

- The estimate of the unknown quantity is computed as the linear function or superposition of the data (plus fixed effects).
- The weights are selected so that in a statistical (expected value) sense:
 1. the difference between the true value and the estimate is zero (unbiasedness)
 2. the squared difference is as small as possible (minimum variance or “best.”)

Basic Ideas

We conceptualize that jointly the unknowns and the observations belong in an ensemble of possible unknown-observation sets. Each member of the ensemble has a probability of being the true one. The model only specifies and the methodology only uses ensemble averages, also known as expected values, of linear and quadratic functions of the variables. Furthermore, the unknown and the observations are statistically related (or “correlated”).

The symbol $E[\cdot]$ indicates averaging, known as expected value. For illustration, for a probabilistically characterized variable z , the mean, the variance, and the average of an arbitrary quadratic function are as follows:

$$E[z] = \mu \quad (1)$$

$$E[(z - \mu)^2] = \sigma^2 \quad (2)$$

$$E[az + bz^2] = a\mu + b(\mu^2 + \sigma^2) \quad (3)$$

where a, b are deterministic variables (in other words fixed numbers).

Next, consider that we have two variables: s with mean μ and variance σ^2 and y with mean μ_y and variance σ_y^2 . Furthermore, the covariance between s and y is C_{sy} .

$$\begin{aligned} E[s] &= \mu, E[(s - \mu)^2] = \sigma^2 \\ E[y] &= \mu_y, E[(y - \mu_y)^2] = \sigma_y^2, E[(s - \mu)(y - \mu_y)] = C_{sy} \end{aligned} \quad (4)$$

These relations express what we know about these two variables. *E.g.*, our best estimate of s is μ with mean squared error σ^2 . They also express the interdependence between two variables. When y is observed, the estimate of s can be improved. We look for the best estimate $\hat{s}$ that is a linear combination of the old estimate and the observed value of y :

$$\hat{s} = \mu + \lambda(y - \mu_y) \quad (5)$$

where λ is a weight. The estimation error is

$$\hat{s} - s = \mu + \lambda(y - \mu_y) - s \quad (6)$$

with expected value 0, meaning that the estimator is unbiased. We computed expected values by treating s and y as random variables with the probabilistic properties defined above.

We select λ by requiring minimum variance, *i.e.*, minimum mean squared error. The mean squared error is

$$\begin{aligned} E[(\hat{s} - s)^2] &= E[(s - \mu)^2 + \lambda^2(y - \mu_y)^2 - 2\lambda(s - \mu)(y - \mu_y)] \\ &= \sigma^2 + \lambda^2\sigma_y^2 - 2\lambda C_{sy} \end{aligned} \quad (7)$$

Setting the derivative with respect to λ equal to 0 we get $2\lambda\sigma_y^2 - 2C_{sy} = 0$, and thus $\lambda = \frac{C_{sy}}{\sigma_y^2}$. Consequently, the best linear unbiased estimator (BLUE) is

$$\hat{s} = \mu + \frac{C_{sy}}{\sigma_y^2}(y - \mu_y) \quad (8)$$

with mean squared error

$$E[(\hat{s} - s)^2] = \sigma^2 - \frac{C_{sy}^2}{\sigma_y^2} \quad (9)$$

We can express the results in terms of the familiar correlation coefficient ρ . Using that $C_{sy} = \rho\sigma\sigma_y$,

$$\hat{s} = \mu + \rho \frac{\sigma}{\sigma_y}(y - \mu_y) \quad (10)$$

with mean squared error

$$E[(\hat{s} - s)^2] = (1 - \rho^2)\sigma^2 \quad (11)$$

Thus, the updated estimate is the old estimate plus a correction that is linear in $y - \mu_y$ and a coefficient that is the correlation coefficient between the observation and the quantity we want to estimate times a ratio of normalizing factors, $\frac{\sigma_y}{\sigma_y}$. The mean squared error depends on the correlation coefficient and vanishes when $|\rho| = 1$.

Application: Kriging

We turn our attention to an interpolation method. Consider a function $z(\mathbf{x})$, where $\mathbf{x}$ denotes case-specific coordinates, like in 1D, 2D, or 3D. An example may be the precipitation over a watershed, or the concentration of a solute in an aquifer, or the pressure inside a reactor.

Given n observations of z at locations with coordinates $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$, our objective is to estimate the value of z at location $\mathbf{x}_0$. A common model is the following:

$$\begin{aligned} E[z(\mathbf{x}_i)] &= \mu, \text{ for } i = 0, 1, 2, \dots, n \\ E[(z(\mathbf{x}_i) - \mu)(z(\mathbf{x}_j) - \mu)] &= C_{ij}, \text{ for } i, j = 0, 1, 2, \dots, n \end{aligned} \quad (12)$$

where μ is the mean and C_{ij} is the covariance between values at points $\mathbf{x}_i$ and $\mathbf{x}_j$.

We simplify the notation by adopting $z_i = z(\mathbf{x}_i)$. The unbiased linear estimator is

$$\hat{z}_0 = \mu + \sum_{i=1}^n \lambda_i (z_i - \mu) \quad (13)$$

The mean squared error is:

$$E[(\hat{z}_0 - z_0)^2] = \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j C_{ij} - 2 \sum_{i=1}^n \lambda_i C_{i0} + C_{00} \quad (14)$$

We select the λ weights to minimize this expression. We set the derivative with respect to each weight equal to 0, thus obtaining a system of n linear equations with n unknowns:

$$\sum_{j=1}^n \lambda_j C_{ij} = C_{i0}, \text{ for } i = 1, 2, \dots, n \quad (15)$$

Solving this system, we obtain the λ values that minimize the mean squared error that becomes

$$E[(\hat{z}_0 - z_0)^2] = C_{00} - \sum_{i=1}^n \lambda_i C_{i0} \quad (16)$$

This approach is known as simple Kriging. In practice, the main challenge is to select appropriate μ and C_{ij} values.

An important variant is when the mean values of y are modeled as the same everywhere but with an unknown value μ . The unbiased linear estimator then is

$$\hat{y}_0 = \sum_{i=1}^n \lambda_i y_i, \text{ where } \sum_{i=1}^n \lambda_i = 1 \quad (17)$$

The mean squared error is given by Eq. (14). The challenge is to find the weights that minimize this expression subject to the constraint that they must sum up to 1. This constrained optimization problem is solved using the method of Lagrange multipliers. We define the Lagrangian

$$\begin{aligned} \mathcal{L} &= \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j C_{ij} - 2 \sum_{i=1}^n \lambda_i C_{i0} + C_{00} \\ &\quad + 2v \left(\sum_{i=1}^n \lambda_i - 1 \right) \end{aligned} \quad (18)$$

then set the derivative of $\mathcal{L}$ with respect to each weight λ and the Lagrange multiplier v equal to 0, thus obtaining a system of $n + 1$ linear equations with $n + 1$ unknowns.

$$\begin{aligned} \sum_{j=1}^n \lambda_j C_{ij} + v &= C_{i0}, \text{ for } i = 1, 2, \dots, n \\ \sum_{j=1}^n \lambda_j &= 1 \end{aligned} \quad (19)$$

This method is known as ordinary Kriging.

The approach can be extended in a number of ways. For example, universal Kriging, where the mean is variable and in the form $\sum_{k=1}^p f_k(\mathbf{x}) \beta_k$, where $f_1, f_2, \dots, f_p$ are known functions of the coordinates $\mathbf{x}$ and $\beta_1, \beta_2, \dots, \beta_p$ are deterministic but unknown coefficients. The main challenge in the application of these methods is in the selection of an appropriate model. Kriging and related issues are covered in books on linear Geostatistics (for example, Kitanidis 1997). See article *Kriging*.

Inverse Problems

Basic Form

We now turn our attention to a formulation that is suitable for solving inverse problem. Inverse problems are estimation

problems for which data alone are not sufficient to provide a unique answer. These problems are underdetermined or ill posed: There are many solutions that reproduce the data. BLUE can handle such problems because it includes probabilistic modeling of the unknown.

We adopt a matrix-vector notation, or else the notation gets out of hand. The unknowns are arranged in an m -dimensional column vector $\mathbf{s}$ and the observations in an n -dimensional column vector $\mathbf{y}$. The relation between the two vectors is linear

$$\mathbf{y} = \mathbf{H}\mathbf{s} + \mathbf{v} \quad (20)$$

where $\mathbf{H}$ is a given n by m matrix, and $\mathbf{v}$ is random with mean $\mathbf{0}$ and covariance matrix $\mathbf{R}$. In many applications $\mathbf{R} \propto \mathbf{I}$, where $\mathbf{I}$ is the identity matrix of size n .

The $\mathbf{s}$ is also random with mean $\boldsymbol{\mu}$ and covariance matrix $\mathbf{Q}$, and $\mathbf{s}$ is uncorrelated from $\mathbf{v}$. Then, $\mathbf{y}$ has mean $\mathbf{H}\boldsymbol{\mu}$ and covariance $\mathbf{H}\mathbf{Q}\mathbf{H}^T + \mathbf{R}$, while the cross-covariance between $\mathbf{s}$ and $\mathbf{y}$ is $\mathbf{Q}\mathbf{H}^T$. Then, following the familiar BLUE methodology, we obtain the following algorithm. First compute $\mathbf{A}^T$, using linear system solvers,

$$(\mathbf{H}\mathbf{Q}\mathbf{H}^T + \mathbf{R})\mathbf{A}^T = \mathbf{H}\mathbf{Q} \quad (21)$$

or, explicitly,

$$\mathbf{A} = \mathbf{Q}\mathbf{H}^T (\mathbf{H}\mathbf{Q}\mathbf{H}^T + \mathbf{R})^{-1} \quad (22)$$

Then, the best estimate $\hat{\mathbf{s}}$ and matrix of mean squared estimation errors $\boldsymbol{\Sigma}$ are

$$\hat{\mathbf{s}} = \boldsymbol{\mu} + \mathbf{A}(\mathbf{y} - \mathbf{H}\boldsymbol{\mu}) \quad (23)$$

$$\boldsymbol{\Sigma} = \mathbf{Q} - \mathbf{A}\mathbf{H}\mathbf{Q} \quad (24)$$

The only requirement is that $\mathbf{H}\mathbf{Q}\mathbf{H}^T + \mathbf{R}$ is invertible. These equations are very general; for example, they can give the simple Kriging equations and are used in the Kalman filter.

Unknown Coefficients in the Mean

Consider now that the mean vector $\boldsymbol{\mu}$ is not fully predetermined but instead is

$$\boldsymbol{\mu} = \mathbf{X}\boldsymbol{\beta} \quad (25)$$

where $\mathbf{X}$ is a known m by p matrix and $\boldsymbol{\beta}$ is an p -dimensional column vector of unknown coefficients. The BLUE method gives the following algorithm (Kitanidis 1995).

First, compute two matrices: the m by n matrix $\mathbf{A}$ and the p by m matrix $\mathbf{M}$ from the linear system

$$\left[\begin{array}{c|c} \mathbf{H}\mathbf{Q}\mathbf{H}^T + \mathbf{R} & \mathbf{H}\mathbf{X} \\ \hline (\mathbf{H}\mathbf{X})^T & \mathbf{0} \end{array} \right] \left[\begin{array}{c} \mathbf{A}^T \\ \mathbf{M} \end{array} \right] = \left[\begin{array}{c} \mathbf{H}\mathbf{Q} \\ \mathbf{X}^T \end{array} \right] \quad (26)$$

The matrix of coefficients is a 4×4 block matrix, with overall size $(n + p) \times (n + p)$. Then, the mean is computed through

$$\hat{\mathbf{s}} = \mathbf{A}\mathbf{y} \quad (27)$$

and the covariance is

$$\boldsymbol{\Sigma} = \mathbf{Q} - \mathbf{X}\mathbf{M} - \mathbf{Q}\mathbf{H}^T\mathbf{A}^T \quad (28)$$

These equations have many applications, like they can yield the ordinary Kriging equations.

The Kalman Filter

The Model

Let us first discuss two important concepts: (1) dynamic system and (2) state-space representation underlying the Kalman filter.

The evolution of many systems encountered in applications can be described by a linear discrete-time state-space structure, as follows:

$$\mathbf{s}(k+1) = \boldsymbol{\Phi}_k \mathbf{s}(k) + \mathbf{u}_k + \mathbf{w}_k \quad (29)$$

where $\mathbf{s}(k)$ is the state at stage k , $\boldsymbol{\Phi}_k$ is a known transition matrix, $\mathbf{u}_k$ is a known (deterministic) input, and $\mathbf{w}_k$ is a random (probabilistically defined) input.

The relation between state and observation is also linear:

$$\mathbf{y}(k+1) = \mathbf{H}_{k+1} \mathbf{s}(k+1) + \mathbf{v}_{k+1} \quad (30)$$

where $\mathbf{y}(k+1)$ is data obtained at $k+1$, $\mathbf{H}_{k+1}$ is a known observation matrix, and $\mathbf{v}_{k+1}$ is a random (probabilistically defined) noise term.

An important part of the model is that the stochastic terms $\mathbf{w}$ and $\mathbf{v}$ that drive the process are modeled as discrete white noise processes, which means the following:

For all k and l ,

$$E[\mathbf{w}_k] = \mathbf{0} \quad (31)$$

$$E[\mathbf{w}_k \mathbf{w}_l^T] = \begin{cases} \mathbf{Q}_k, & k = l \\ 0, & k \neq l \end{cases} \quad (32)$$

$$E[\mathbf{v}_k] = \mathbf{0} \quad (33)$$

$$E[\mathbf{v}_k \mathbf{v}_l^T] = \begin{cases} \mathbf{R}_k, & k = l \\ 0, & k \neq l \end{cases} \quad (34)$$

$$E[\mathbf{w}_k \mathbf{v}_l^T] = \mathbf{0} \quad (35)$$

$$E[\mathbf{s}(0) \mathbf{v}_k^T] = \mathbf{0} \quad (36)$$

$$E[\mathbf{s}(0) \mathbf{w}_k^T] = \mathbf{0} \quad (37)$$

The model is versatile and can be applied to many actual problems. The state-space structure is a natural way to represent the evolution of most systems. The crucial idea is that $\mathbf{s}(k)$ is all we need to know about the system and its past history in order to describe its evolution at $k+1, k+2, \dots$. Many models are linear or can be approximated as linear. The representation of uncertainty as additive white noise is a modeling assumption of proven usefulness. When the assumptions of serial independence in $\mathbf{w}$ or $\mathbf{v}$ and independence between $\mathbf{w}$ and $\mathbf{v}$ are violated, there are ways to modify the model to handle these issues (for example, Grewal and Andrews 2015, p. 200).

Kalman Filter Algorithm

The Kalman filter algorithm is repeated at every step, which is defined as the transition from stage k to $k+1$. We may omit the index k or $k+1$ for Φ , $\mathbf{u}$, $\mathbf{w}$, $\mathbf{Q}$, $\mathbf{H}$, $\mathbf{v}$, and $\mathbf{R}$. (In other words, the same recursion formulas will be used, even though these quantities may be different each time.)

The state of the system at time k given observations up to time k has mean $\hat{\mathbf{s}}(k|k)$ and covariance $\Sigma(k|k)$. These two quantities summarize all information from the initial conditions and measurements up to time t .

The objective is to obtain the state of the system at time $k+1$ given observations up to time $k+1$, described through $\hat{\mathbf{s}}(k+1|k+1)$ and $\Sigma(k+1|k+1)$. This is accomplished in two steps: prediction (also known as forecasting or extrapolation) and updating (also known as correction or conditioning).

Prediction

The one-step prediction problem is to find the mean and covariance of $\mathbf{s}(k+1)$ given information up to time k and utilizing the state transition equation Eq. (29).

$$\hat{\mathbf{s}}(k+1|k) = \Phi \hat{\mathbf{s}}(k|k) + \mathbf{u} \quad (38)$$

$$\Sigma(k+1|k) = \Phi \Sigma(k|k) \Phi^T + \mathbf{Q} \quad (39)$$

Updating

Now, we must combine two sources of information regarding $\mathbf{s}(k+1)$: Information up to k , which is what we got at the prediction step, and new information, from data $\mathbf{y}(k+1)$. This is the updating step. We already know the solution to this problem (see preceding section Inverse Problems). The most intuitive form of the equations for the correction step is the *linear feedback* or *linear correction* form, given next:

$$\begin{aligned} \hat{\mathbf{s}}(k+1|k+1) &= \hat{\mathbf{s}}(k+1|k) \\ &\quad + \mathbf{K}(\mathbf{y}(k+1) - \mathbf{H}\hat{\mathbf{s}}(k+1|k)) \end{aligned} \quad (40)$$

where

$$\mathbf{K} = \Sigma(k+1|k) \mathbf{H}^T [\mathbf{H} \Sigma(k+1|k) \mathbf{H}^T + \mathbf{R}]^{-1} \quad (41)$$

The covariance is

$$\Sigma(k+1|k+1) = \Sigma(k+1|k) - \Sigma(k+1|k) \mathbf{H}^T \mathbf{K}^T \quad (42)$$

The updated covariance is the prediction covariance minus the reduction through the measurements.

The linear feedback coefficient $\mathbf{K}$ is known as the Kalman gain. The updated estimate is the predicted mean plus a correction that is linear in the feedback. When the feedback is zero, there is no need for correction. Otherwise, the correction is weighted by the Kalman gain.

Kalman Filter with Unknown Inputs

In many applications, the unknown input that drives the dynamic system cannot be well captured through a white noise process, as when the input is sometimes near zero and sometimes quite pronounced. We add the term $\mathbf{G}_k \boldsymbol{\theta}_k$, where $\mathbf{G}_k$ is an $m \times p$ matrix of known coefficients and $\boldsymbol{\theta}_k$ is a $p \times 1$ vector of unknown coefficients (Kalman filter with unknown inputs).

$$\mathbf{s}(k+1) = \Phi_k \mathbf{s}(k) + \mathbf{u}_k + \mathbf{G}_k \boldsymbol{\theta}_k + \mathbf{w}_k \quad (43)$$

The solution is obtained using the familiar BLUE methodology (Kitanidis 1987).

Successive Linearization

BLUE methods can be adjusted to yield approximate solutions to nonlinear problems. For example, consider the inverse problem with a nonlinear forward map

$$\mathbf{y} = \mathbf{h}(\mathbf{s}) + \mathbf{v} \quad (44)$$

when $\mathbf{h}$ is the n -dimensional vector function of an m -dimensional vector. A common approach is the method of successive linearization. At each step of the iterative procedure we start with an initial estimate of $\tilde{\mathbf{s}}$ and we seek a better estimate $\hat{\mathbf{s}}$. Let the derivative of $\mathbf{h}$ with respect to $\mathbf{s}$ at $\tilde{\mathbf{s}}$ be $\tilde{\mathbf{H}}$:

$$\tilde{\mathbf{H}} = \left. \frac{\partial \mathbf{h}}{\partial \mathbf{s}} \right|_{\mathbf{s}=\tilde{\mathbf{s}}} \quad (45)$$

The n by m matrix $\tilde{\mathbf{H}}$ is known as the Jacobian matrix. Assuming that $\mathbf{s}$ is close to $\tilde{\mathbf{s}}$, approximate,

$$\mathbf{h}(\mathbf{s}) = \mathbf{h}(\tilde{\mathbf{s}}) + \tilde{\mathbf{H}}(\mathbf{s} - \tilde{\mathbf{s}}) \quad (46)$$

Then, the observation equation can be rewritten as

$$\tilde{\mathbf{y}} = \mathbf{y} - \mathbf{h}(\tilde{\mathbf{s}}) + \tilde{\mathbf{H}}\tilde{\mathbf{s}} = \tilde{\mathbf{H}}\mathbf{s} + \mathbf{v} \quad (47)$$

This is the familiar linear observation equation except that the matrix of observation matrix and also the data vector depend on the most recent estimate $\tilde{\mathbf{s}}$. So, we can use the familiar BLUE equations by using:

$$\begin{array}{ll} \tilde{\mathbf{H}} & \text{instead of } \mathbf{H} \\ \tilde{\mathbf{y}} & \text{instead of } \mathbf{y} \end{array} \quad (48)$$

This approach, which we call the *basic iteration*, is simple enough:

1. Start with a reasonable initial estimate $\tilde{\mathbf{s}}$.
2. Compute $\tilde{\mathbf{H}}$ and $\tilde{\mathbf{y}}$.
3. Use the equations for the solution of the linear problem to obtain $\tilde{\mathbf{s}}$.
4. Update $\tilde{\mathbf{s}} = \hat{\mathbf{s}}$ and return to step 1 until convergence is achieved.

Variable Transformation

A related issue is that of variable transformation. Suppose the unknown is conductivity, such as the hydraulic conductivity of a porous medium, or the electric conductivity of a fluid or a solid. This quantity cannot be negative and in some cases it makes no sense to assume it could be zero. However, the BLUE approach does not make a provision for this constraint. One way to circumvent this problem by applying the BLUE methods to a nonlinear transformation of the variable, like the logarithm of conductivity that can be positive and negative (e.g., Tarantola 2005).

Algorithms for Large Problems

Requirements for higher-resolution solutions and trends in data collection technologies lead to problems with increasingly larger numbers of unknowns and observations. The storage and computational cost of implementing the standard or “textbook” methods increases at least quadratically with m . Thus, despite the rapid improvement in computational technology, they become practically impossible to apply for problems of, say $m \sim 10^6$.

However, special technologies have been developed for large problems (reviewed in Ghorbanidehno et al. 2020). Some of these methods use low-rank approximations of covariance matrices, which are easy to store and use in computations, and matrix-free methods, which means that the Jacobian matrix $\mathbf{H}$ is not explicitly computed. One such method for inverse problems is the principal component geostatistical approach (PCGA) (Kitanidis and Lee 2014). The most popular such method is the ensemble Kalman (EnKF), which is described in the next section.

The Ensemble Kalman Filter

The ensemble Kalman filter (EnKF) (Evensen 1994, 2009) is an ingenious in its simplicity implementation of the Kalman filter with computational costs that scale roughly linearly with m , and thus can be used to solve large problems, such as in atmospheric modeling or meteorological forecasting.

The foundation of this approach is that a random vector $\mathbf{x}$ can be represented approximately through an ensemble of N *realizations* or samples from its pdf. For example, the state vector of a dynamic system is given through a matrix with columns the N equiprobable independent realizations from its distribution.

$$\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N] \quad (49)$$

where $\mathbf{x}_i$ is m -dimensional column vector. See article *Ensemble Kalman Filter*.

Relation to Bayesian Methods

Most recent developments in data analysis and estimation are within the realm of Bayesian analysis. The BLUE methodology gives the same results in most cases as the Bayesian approach with Gaussian distributions. Rather than thinking of the two approaches as competitive, one should consider that they provide complementary insights. These results, whether interpreted as BLUE or Bayesian analysis, remain among the most commonly used in practical applications.

Machine learning (ML) methods, (see, for example, Geron 2019) have made great strides in dealing with the same problems where BLUE methods are popularly used. However, such methods typically require much more data to train and implement.

Summary and Conclusions

Best linear unbiased estimation (BLUE) methods are probability-based inference methods that utilize only the first two statistical moments, mean and variance-covariance values, instead of complete probability distributions. In addition to requiring little information, BLUE methods are computationally efficient because they rely on linear (like matrix-vector multiplications) operations. The methodology seeks an estimate that is a linear function of the data that, in an average sense over the ensemble of possible values, has an error that (a) has zero mean and (b) has a squared value that is as small as possible. The methodology has been extended to deal with some nonlinear problems through linearization. New algorithms, like EnKF, allow us to solve large-dimensional problems in a computationally efficient way. Among the many applications of BLUE, it is worth mentioning the following: (1) interpolation methods, like Kriging; (2) inverse problem applications; and (3) dynamic data assimilation methods, using various flavors of Kalman filter. Although more sophisticated methods have been developed, mainly in the Bayesian and machine learning frameworks, they usually require more information and are computationally more expensive to run than the BLUE approach.

Big Data

Xiaogang Ma

Department of Computer Science, University of Idaho,
Moscow, ID, USA

Definition

It is hard to use a single definition to cover all the characteristics of big data. A general understanding is that big data are a field dealing with data sets that are too large or complex for traditional platforms and tools to handle. The term “big data” first appeared in the mid-1990s. Later, Laney (2001) used the three Vs to describe the dimensions of challenges in data management: Volume, Variety, and Velocity. The three Vs have been well received and have become a common framework to describe the characteristics big data. Other V terms, such as Value, Veracity, and Variability have also been used in various publications to extend the discussion on big data. In the original three Vs, Volume refers to the size of data. So far, big data are reported in terabytes or petabytes, and exabytes and zettabytes are already on the horizon. Variety refers to the heterogeneous structures and types in data. Big data often include structured, semi-structured, and unstructured formats, especially the latter two. Velocity refers to the rate at which data are generated and processed. The advancement in hardware and platform has led to real-time or near real-time generation of massive data sets, such as those on social media. In the other three Vs, Value means that a high value can be obtained from big data though the value density is low in the raw data. Veracity refers to the (in)reliability in the source and quality of data. Variability refers to changing rate or other characteristics in the data flow. In recent years, a topic under discussion among data scientists is the transformation from “big data” to “smart data.” In comparison, in the community of geomathematics and geoinformatics researchers

have been working on both data integration and intelligent analysis. Such discussion and progress reflect people's desire for better platforms and tools to support their work with big data. Most recently, the FAIR principles (Findable, Accessible, Interoperable, Reusable) have set up a roadmap for refining the capabilities of data sharing and reuse in the cyberinfrastructure. Data are not isolated from other objects in research activities. To efficiently implement FAIR principles, we also need to consider many other entities, agents, and activities in a scientific process, such as research activities, samples, software packages, data analysis methods, publications, organizations, researchers, research questions, and more. With clear identification of those objects and meaningful connection among them, we will be able to develop functions to make smart recommendations on datasets to retrieve, hypotheses to explore, methods to use for data analysis, and researchers to collaborate with. Eventually we envision a so-called smart data ecosystem to leverage big data and facilitate new discoveries in geosciences.

Introduction

The rapid development in facilities for data generation and collection, infrastructure for data storage and transmission, and social and cultural change in data sharing and reuse enable the big data of nowadays. In geoscience, scientists are now able to access massive datasets on the Internet, and many large-scale scientific projects have been leveraging big data, machine learning and high performance computation to make ground-breaking discoveries in geoscience (Gil et al. 2019). We envision that global open data and open science endeavors (Nosek et al. 2015) will result in an emergent smart data ecosystem: a complex network that includes data, researchers, research questions, publications, software, instruments, institutions, data repositories, web-based search engine results, and more. The interconnection and interaction of people, data, scientific hypotheses and other facilities will finally lead to intercreation in geoscience in the coming decades. Yet, the machine-readability of key components in the data ecosystem remains a very challenging task. There are various objects and relationships in the ecosystem, and many of them lack a common mechanism for definition, metadata encoding, identifier, and interconnection – for example, via an Application-Programming-Interface (API). Taking data as an example, it is only recently that the global science community developed the FAIR principles: findable, accessible, interoperable, and reusable (Wilkinson et al. 2016) though means for each component have been in existence for decades on the Internet. The geoscience community has taken pioneering steps in developing implementation plans and best practices of FAIR (Stall et al. 2019).

Besides data, there are also standard digital representation of other objects, such as identifiers and metadata schemas for software packages, researchers (e.g., ORCID), organizations, samples, and research activities. Nevertheless, the interconnections among those objects are still limited, and the data ecosystem is still far from mature enough to provide efficient support to research activities. Many researchers are still spending about 80% of their time on data preparation before the actual analysis and knowledge discovery can be conducted (i.e., the 80/20 rule). To achieve a smart data ecosystem for geoscience, there are still many developments to be explored.

Efficient and precise data recommendation and discovery will bring significant improvements to geoscience research with big data. In the past decades, several global geoscience data infrastructures have been established through various communities of practice. For example, data repositories of many geoscience disciplines have been built in the USA through the support from NSF and other sources. Yet, facing such a flourishing data environment, researchers still often struggle to find datasets appropriate for their research questions or interests. A data infrastructure does not constitute a list of isolated data repositories. Instead, tools are required to make interconnections among data sources to focus on research questions and, more importantly, to make context-aware recommendations of data to researchers, research questions, or research programs to help data discovery. The core of such data recommendations is the similarity between a dataset and other objects such as research questions, software packages, and researchers. Algorithms for similarity computation and recommendation are usually developed by using records from the semantic representation of data and various other objects, i.e., a machine-readable encoding of what these objects “mean” or are defined as. Any enriched metadata and relationship descriptions in a semantic representation will help reduce the uncertainty of input data for those algorithms. With minor adaptation, similarity algorithms will also apply to other objects, such as recommending software packages to a dataset or a research question, recommending a collaborator to a researcher, or recommending a research proposal to a grant program.

Moreover, data-intensive geoscience of nowadays is often cross-disciplinary, and needs teamwork to assemble experts with different knowledge backgrounds. This calls for theories and approaches to efficiently unite expertise in computer science, mathematics, statistics, information science, and geoscience, to discover and interpret interesting patterns in the data. We want to call for communities of practice to shift the time that geoscience researchers spend on data preparation into innovative work in scientific discovery. The goal is to transform the 80/20 rule in data-intensive geoscience research into 50/50 or even 20/80. This entry does not provide detailed solutions to certain small questions in big data. Instead, it

intends to draw directions from the broad geomathematics and geoinformatics community about the characteristics of big data and smart data, leading to a call to action, with the hope of seeing increasing improvements, extensions, and discussions of progress in the near future.

Infrastructure and Characteristics of Big Data

Big data are the outcome of many infrastructure and technological developments in the past decades (Kitchin 2014). The rise of computers in the 1950s brought digitization to data. The appearance of the Internet in the 1970s enabled computers to be linked together to transmit data. The widespread use of personal computers in the 1980s and 1990s transformed the mode of how geoscientists do their job. The fast development of the Internet and the Web in the 1990s and 2000s enabled a lot of data portals, especially those built by governmental agencies. The Internet of Things, linked open data, cloud computing, and machine learning in the 2010s quickly increased the rate and scale of data generation and processing. In comparison, those developments in infrastructure and technologies have also facilitated the evolution of mathematical geosciences. Merriam (2004) summarized the six stages of geomathematics: Origins (1650–1833), Formative (1833–1895), Exploration (1895–1941), Development (1941–1958), Automated (1958–1982), and Integration (1982–). The three stages since the 1940s were absolutely characterized by the application of computers. In particular, we are able to see the quick development of spatial statistics, simulation and modeling, and large dataset processing to tackle all the steps in a geoscience workflow. Moreover, geoscience data nowadays are not only being integrated but also being processed with many intelligent technologies.

The rapid development in infrastructure and technology enables big data and bring new opportunities to various organizations and individuals. For example, NASA is one of the biggest generators of geoscience data across the world. An article published in 2019 reported that NASA was generating 12.1 TB of data every day in 2016 (Shannon 2019). Those data were from nearly 100 missions and thousands of sensors, instruments, and platforms around the Earth and space. The article also anticipated that some of NASA missions will soon be able to generate 24 TB of data every day. Besides its long-term data storage programs such as the Earth Observing System Data and Information System (EOSDIS) and the Distributed Active Archive Centers (DAACs), NASA is also collaborating with commercial organizations such as Amazon and Google to use external cloud platforms for data storage. To efficiently handle and process the big data, NASA has put a lot of efforts on machine learning algorithms and artificial intelligence solutions, with the aim to realize seamless connections between data generation, transmission,

cleansing, processing, and decision-making. For individuals, with the thriving approaches of open data, crowdsourcing, and citizen science, anyone can be a data contributor and also a data user. Governmental agencies such as NASA and USGS are making massive geoscience data open and free to use. Scientists are able to analyze real-time data stream transmitted back from a vessel carrying out investigation in the ocean. A geologist in the field can take a photo of an outcrop with a smartphone and then use an app to help identify the rock and mineral types. Publishers are establishing new mechanisms to allow or even require authors to publish their data with papers. A student can paste a question on social media, then many people will suggest publications, datasets, or software packages for him.

The usage of the infrastructure, including Internet, data, algorithms, and computing facilities is being leveraged to a new level. They are not only capable of representing what is known, but can also uncover the origin and reason and help generate ideas for exploring new findings. The skill-set of a geoscientist in the era of big data should include not only the expertise from traditional geoscience disciplines but also many new theories and methods from other disciplines. Essentially, geoscientists who plan to conduct data-intensive research should be aware of the characteristics of big data. Besides the six Vs (Volume, Variety, Velocity, Value, Veracity, and Variability) mentioned above, a few other characteristics were discussed by Kitchin (2014), including exhaustivity, resolution, indexicality, relationality, and flexibility. The “exhaustivity” means that big data projects tend to capture datasets for the whole population or much larger sampling sizes than traditional small data studies. For example, a very recent report on NY Time (Koettl et al. 2020) used satellite images, videos taken by first responders, social media posts, and public radio reports to analyze the patterns of the Almeda fire at the Rogue Valley in southern Oregon and help discover the reasons for the huge destruction caused by the fire. The slogans in big data community, such as “more is better” or “when you can, keep everything” perhaps are driven by the belief that larger data population will increase the chance to find new insights. Nevertheless, the extremely large data also require special methods and tools for storage and processing. The “resolution” means datasets of fine graininess. A typical example is remote sensing images. The “indexicality” means that datasets can have unique and persistent labels and identifiers. For example, Digital Object Identifiers (DOIs) are increasingly used in data sharing and reuse. The “relationality” means that different datasets can be conjoined to answer new questions. The intention is that the sum of data is better than the parts. An interesting object that might appear in the future is “data study” or “data review,” which is similar to the review article in journal publications. The “flexibility” means that big data systems are flexible in

structure and volume. New attributes can be added easily, and the scale of data collection can expand quickly.

Open Data to Change the Mode of Geoscience

Openness, provenance, and reproducibility are readily recognized as features of science nowadays (Nosek et al. 2015; Gil et al. 2019). Increasingly, scientists share data as a part of their outputs, and they also use data shared by others to advance their own research (Kitchin 2014; Boulton et al. 2015). Open science and open data endeavors not only promote communication and reproducibility of scientific outputs, but also strengthen public trust and inform effective decision- and policy-making (Tilmes et al. 2013). In a provenance-aware cyberinfrastructure, if we treat a dataset as an object, then it is related to other objects such as: data creator, scientific subjects, data type, software packages, source and derived publications, data repositories, research questions, samples, instruments, research programs, institutions, and more. The technological framework of the Semantic Web (Berners-Lee et al. 2001) provides the necessary capabilities for categories, identifiers, descriptions, and interconnections among the above-mentioned objects. Thus, Semantic Web is an appropriate environment to capture provenance of open data (Groth and Moreau 2013). To facilitate a virtuous circle of data sharing, discovery, reuse, publication and sharing in the data ecosystem, good quality data, metadata, and provenance must all be published. As Gil et al. (2019) pointed out, provenance and reproducibility will be an essential feature of geoscience contributions in the future. A better semantic representation for objects and their interrelationships in open data and open science will help lead to many innovative studies: enriched metadata of datasets for web crawlers, evaluation and ranking of data FAIRness, and provenance tracing of shared data, just to name a few. This will in turn lay the ground for other innovative work, such as evaluating the long tail of data reuse, reproducibility of scientific workflows by tracing connected objects, and scalability of machine-readable networks.

The importance of open data for scientific innovation has not only been addressed by funding agencies but also by the broader international scientific community. Researchers themselves have been working on principles, guidelines, and implementation plans to facilitate better data management and stewardship using cyberinfrastructure. A very recent work is the FAIR data principles (Wilkinson et al. 2016). In FAIR, Findability means data can be found by common search tools. Accessibility means both metadata and data are able to be retrieved and examined. Interoperability means comparable data will be used together through common vocabulary and formats. Reusability means that data are able to be used by others as a result of good metadata,

provenance, and licenses. The FAIR principles are becoming a growing consensus among different disciplines to improve the quality of open data, including geoscience (Stall et al. 2019). Given the massive amounts of data, it is hard to implement the FAIR principles manually. Tools and platforms are needed to help researchers to check different parts of the FAIRness of their data, and complement the missing or incomplete information to meet the FAIR principles. The enriched data will also be easier for users to discover, access, and reuse. To translate FAIR principles into actionable steps, a system of metrics is needed to represent the detailed parts in those principles, and then to be implemented in the automated tools and platforms mentioned above. Thus, the FAIRness of data will be measurable through the metrics embedded in the tools and platforms.

In this entry, the many objects accompanying open data and big data are called an ecosystem because they form a socio-technical system (Berman et al. 2018). Besides the many technological elements and barriers discussed above, there are also considerable social, ethical, and legal topics related to data. A data creator and/or owner needs to consider their rights and licenses when publishing data. A data user needs to know the license before using other people's data. Moreover, appropriate technologies are needed to accredit data sharing. The academic community needs to change its culture and standards to take data management and sharing as part of research performance measures. The government needs to develop suitable guidelines to encourage best practices in data stewardship and prevent harmful consequences. In today's cyberinfrastructure, researchers are able to share not only data but also many other resources, such as software code, methods and techniques, and workflows. Those objects, their attributes, and their relationships form the technological foundation of the data ecosystem (Berman et al. 2018; Noy et al. 2019). One part of this ecosystem is a way to track the provenance of objects and another is a design of appropriate incentives. These in turn imply the design of appropriate metrics to be used as resources in articulating how incentives lead to value. Therefore, what needs to be considered is the design in the larger context of the science enterprise, that is, the interconnection and interaction of factors and objects in a data ecosystem.

A Smart Data Ecosystem for Geoscience: A Vision for the Future

In recent years, the geoscience community has made noteworthy achievements in regard to data facility building blocks, infrastructure for interoperability, and informatics applications (Nativi and Fox 2010; Yang et al. 2019). Geoscientists are currently taking a leadership role to turn the FAIR principles of open data into practice (Stall et al. 2019).

Funding agencies are increasing their support of data-intensive research; an example of which is one of NSF's ten big ideas on Harnessing the Data Revolution (HDR). Various efforts on best practices are evident in communities such as Research Data Alliance (RDA), NSF-EarthCube, AGU-Earth and Space Science Informatics section (ESSI), GSA-Geoinformatics division, and Earth Science Information Partners (ESIP). For instance, the EarthCube and ESIP communities have conducted fruitful applications of schema.org for geoscience data discovery (Lingerfelt et al. 2017), which was even earlier than the release of the Google Dataset Search (Noy et al. 2019). Such works and discussions demonstrate geoscientists' desire to transform big data into smart data and thus gain better support of data for their research.

To create a smart data ecosystem and transform the 80/20 rule, better machine-readable metadata and more automation are needed in the current cyberinfrastructure. Structured and enriched semantic representation is needed for both data and other objects in the data ecosystem. Work on FAIR metrics however is still in an early stage. Many FAIRness pilot systems applied a questionnaire approach. A user needs to answer questions step by step in order to receive an over-all evaluation result. In Wilkinson et al. (2017), part of the metrics design is machine-readability and protocol for metadata access, but there is no pilot portal for the design yet. Machine-readable FAIR metrics may be the key to increased automation in the data ecosystem. Those metrics are derived from the detailed items listed in each of the four FAIR principles. For example, the metrics need to at least include the scheme of unique and persistent identifiers for data, the metadata associated with each data identifier, the protocol for data and metadata access, ontologies, vocabularies and other community standards used in the data, provenance about the origin of the data, and licenses for data usage, just to name a few. Based on those metrics, tools and platforms will be built to set up a pipeline that helps users examine and enrich the standardization, structure, and description of their data and metadata. The process of data and metadata sharing is bottom-up and needs contribution from various individuals and organizations, and a framework for such activities is the essential foundation. Semantic representation, machine-readable metrics, and interconnections among objects are able to represent a framework of structured information. Even light and simple semantics in the framework will increase the machine-readability a lot, such as the structured data markup enabled by schema.org for web pages (Noy et al. 2019). With clear identification of objects in the data ecosystem and meaningful connections among them, functions can be developed to make smart recommendations on datasets to retrieve, hypotheses to explore, functions to use for data analysis, and researchers to collaborate with.

Eventually, a smart data ecosystem will implement the FAIR principles, leverage various open data resources, and

facilitate new discoveries in geoscience. Data-intensive geoscience research of nowadays has several characteristics: research question-focused, cross-disciplinary, and teamwork with complementary expertise (Hazen et al. 2019; Shipley and Tikoff 2019). Geoscience research also benefits from the recent discussion and development on theories and methods of data science. The above narrative identifies the following topics of interest for future methodological and technological developments towards a smart data ecosystem for geoscience: (1) machine-readable FAIR metrics for open data; (2) representation of objects and relationships in the data ecosystem for provenance tracing; (3) intelligent recommendation and suggestion of data and other resources in open science; and (4) data science methods in cross-disciplinary geoscience research.

Technological Approaches Toward a Smart Data Ecosystem

The following four subsections will introduce more details of a few technological topics that can be explored in the future. It is noteworthy that they are just part of the many research topics in big data. They have a focus on data sharing, management, and reuse. Many other topics in machine learning and data mining are not covered here.

Machine-Readable FAIR Metrics of Geoscience Data

As mentioned above, to put FAIR data principles into practice in geoscience, machine-readable FAIR metrics data must be developed. There are community initiatives focusing on different aspects of those principles, such as data identifiers, data types, domain-specific vocabularies, data citation, and a data seal of approval for repositories. Research is needed to leverage the existing building blocks to automate a set of metrics to represent the detailed elements in the FAIR principles, and incorporate those technological components and interfaces into new tools. Those tools will enable individual researchers to evaluate and improve the FAIRness of their data before sharing. The tools will also be used by data facility managers to check the FAIRness of published data and make updates.

Semantic representations for FAIR principles, such as ontologies, must be further developed. They will define/inform key elements in the machine-readable FAIR metrics. The knowledge engineering work for those semantic representations will need to incorporate community standards such as the Provenance Ontology (PROV-O), schema.org/Dataset, and the Dataset Catalog recommendation (DCAT) as well as the existing experimental FAIR ontology studies. To employ those semantic representations (e.g., ontologies) in tools for FAIR metrics evaluation, the ideal situation is an automated or semiautomated process. In such a process, the tools will access existing services to generate results for the metrics,

without or with minor user control. To achieve such automation, a number of existing services and building blocks for open data should be reflected in the FAIR metrics, and interfaces and interactions to them should be established in the tools. Those services and building blocks include DataCite, Data Type Registry, Linked Open Vocabulary Service FAIR sharing standard and vocabulary registry, Data Citation Index, and dataset attributes specified in schema.org/Dataset, to name a few. Future developments in cyberinfrastructure will bring more building blocks for all aspects of the FAIR principles and automate the FAIR metrics evaluation process.

Semantic Representation of Scientific Workflows for Provenance Documentation

The current technological environment for a data ecosystem is the Web, wherein data are but only one of the many objects that are involved in a scientific research workflow. On the Web, researchers will follow linked identifiers to such objects and their corresponding metadata, which in turn often document the provenance of scientific workflows. Increasingly, metadata can be retrieved through object identifiers (often Uniform Resource Locators (URLs)), such as metadata of publications and data. A workflow includes various types of objects, and the metadata of those objects provide sources for provenance documentation. In the past decade, researchers have made progress on identifiers of many types of objects in the data ecosystem. Besides DOIs for publications, recent initiatives include ORCID for researchers, DataCite and DOIs for data, IGSN for geo-samples, OrgID for organizations, RAiD for research activities, and more. Most of those identifiers provide an API service for accessing associated metadata. Those metadata contain contextual information that can be used in subsequent data analysis. For example, Bohannon (2017) showed how to use ORCID metadata to find migratory patterns of scientists over the course of their careers. There have also been experimental studies trying to make connections among those identifiers, such as the ODIN work between ORCID and DataCite, which was able to identify and connect scientists and datasets across multiple services.

Previous successful work on provenance documentation of workflows stands ready to be extended. In the Global Change Information System (GCIS), various objects in climate assessment and reporting were recognized as classes and properties in a new mixture of science and provenance terminology: the GCIS ontology (Tilmes et al. 2013). The collected provenance in GCIS provided structured inputs for the traceability and reproducibility of scientific workflows (Zeng et al. 2019). URLs were used as object identifiers in GCIS. For example, a URL (<http://data.globalchange.gov/article/10.1080/01490419.2010.491031>) was used to represent an article. It points to a web page with detailed metadata about the article, and also the connections between this article and other objects, such as where it was referenced, the source data used

in the article, the figures derived from this article, and more. In the Deep Carbon Observatory (DCO) – Data Science program, the Global Handle System was used to assign a unique and resolvable identifier (i.e., a handle) to each object in the DCO data portal (Ma et al. 2017). The object types were further defined in the DCO ontology to give specific machine-readable meanings of those objects. Our experience of knowledge engineering and semantic representation shows that it is also beneficial to refer to the existing standard ontologies and community best practices to avoid redundant work.

Context-Aware Data and Resource Recommendation for Geoscience

To reduce the time that researchers spend on data search and manipulation, and change the 80/20 rule, one approach is to make data recommendations that match researcher needs by using the idea of scientific similarity. Existing algorithms on similarity computations must be improved to make finer recommendations. Similarity computations have been a continuous research topic in the Semantic Web community, and have also received attention in geoscience (Zheng et al. 2015). Similarity will be computed between data and a researcher, data and a research question, data and methods, and more. Results of such similarity computation will provide suggestions for data recommendations. For example, if the similarity between a dataset and researcher is very high, then it is verily likely that the researcher can make use of the data in his work, so the dataset can be recommended to the researcher. Besides data, similarity computations have been conducted for various other objects, such as software programs, research topics, collaborators, and grant programs. In a data ecosystem, recommendations of those resources and objects can also be made based on the result of similarity computation.

The results of similarity computations are able to be used in many ways in a data ecosystem. For instance, if the similarity between a dataset and a researcher is computed, the resulting similarity value represents to which extent the dataset matches the researcher. The similarity value is a key input for making a data recommendation or not. However, similarity alone is just one of many components to be considered in making recommendations. For example, to make finer recommendations of data to researchers, collaborative filtering (Herlocker et al. 2004) is a way to be used. Collaborative filtering considers users' contributions such as ratings or reviews about items in recommendation making. It is based on the theory that similar users have similar patterns of rating behavior, and similar items obtain similar ratings. Collaborative filtering takes a matrix of existing user-item ratings as the main source of input, such as the data citation records. In a data ecosystem, we anticipate many kinds of user inputs and feedback will be obtained and used in collaborative filtering to improve the precision of resource recommendations.

Data Science Approaches for Geoscience in the Era of Big Data

The theoretical foundation of data science is under fast development, and will benefit from many existing disciplines such as computer science, statistics, mathematics, information science, and domain-specific applications (Fox and Hendler 2014). Geoscience has experienced many challenges and opportunities over the last 20 years and has made changes in their infrastructure in response to the emergent data ecosystem. However, nascent advances in international communities, spurred by RDA, CODATA, EUDAT, NSF-EarthCube, and other communities offer an inflection point for greater capabilities (such as those mentioned in previous sections). Data-driven geoscience often needs multidisciplinary collaboration and teamwork of researchers from different knowledge backgrounds. This feature will potentially make science of team science necessary in geoscience. The practices of team science in geoscience will in turn contribute to the theoretical foundation of data science. The data ecosystem is underpinned by abundant data sources, and by computational facilities, such as Giovanni, IRIS, HydroShare, and others. Progress of geoscience in the coming decade needs renewed attention to both data integration and intelligent analysis.

Exploratory data analysis will be an effective way to tackle big data in geoscience. Similar to many other disciplines, geoscience conventionally applies the hypothesis-driven research method in the research process. In a data ecosystem, geoscience researchers may often face such a situation: while plenty of data are already collected, there is no research hypothesis. The method of exploratory data analysis, which has been proven functional in the domain of statistics (Tukey 1977), may offer clues for hypothesis generation in geoscience. The term “exploratory” explains the purpose of the method: it is flexible and will help look for things that we believe are not there or to be there (Tukey 1977). Exploratory data analysis is comparable to abduction in an iterative process of data-driven discovery (Hazen et al. 2019). Here abduction means forming a plausible explanation for an observation before deduction and induction are taken.

Science of team science can be applied to leverage the multidisciplinary expertise in big geoscience projects. Science of team science studies focus on collaborative and team-based research and elaborate strategies and methods to enhance the effectiveness of science process and outcomes (Grudin 1994). In a recent report released by the National Research Council, recommendations have been made on how to enhance the effectiveness of team science (NRC 2015). One recommendation is about how to use research networking tools in team assembly and task analysis. A key topic in science of team science is to obtain a better understanding of the multi-network structure of scientific collaboration. A network is a structure made up of a set of objects (i.e., nodes), the attributes of the objects, and the

interrelationships (i.e., edges) between those objects. In the data ecosystem, the various types of objects and relationships form complex networks, and methods are needed to gain insights into them.

Summary and Conclusions

Geoscience, like many other disciplines, faces the challenges and opportunities of big data. A smart data ecosystem will significantly shift the time that researchers spend away from data cleansing and preparation into data analysis and scientific discovery. Although cyberinfrastructure development in the past decades has provided a new and powerful data ecosystem, the full potential of the ecosystem is yet to be explored, and many extensions still need to be developed to make such an ecosystem smarter. This entry provides a brief review of the concepts in big data, open data, and open science and offers a perspective on future work that should be explored, such as machine-readable and automated FAIR metrics of open data, semantic representation of key components in the data ecosystem, algorithms for similarity computation and resource recommendation, and network analysis to facilitate the science of team science. Many existing platforms, services, and building blocks are able to be leveraged, such as those in DataCite, Data Type Registry, Linked Open Vocabulary Service, FAIR sharing standard and vocabulary registry, and Data Citation Index. Such extensions and developments inherently call for participation from communities of practice including many stakeholders. A new capacity for data-intensive geoscience, once established, is able to be transferred to other disciplines with minor adaptation, and will serve as a functional foundation for many new research paths to explore big data.

Definition

Binary morphology encompasses all operators from mathematical morphology (MM) on binary images. MM operators are defined on a complete lattice. Binary images constitute a specific lattice. This allows the definition of the MM operators to be simplified. In this entry we shall give an overview of different binary morphological operators. Detailed explanation of these operators can be found in their respective

chapters and the books Najman and Talbot (2013), Soille (2004), and Dougherty and Lotufo (2003).

A binary image can be represented as a set in $\mathbb{R}^2$ or $\mathbb{Z}^2$. Equivalently, one can also represent it as a function, $f: E \rightarrow \{0, 1\}$ where E is either $\mathbb{R}^2$ or $\mathbb{Z}^2$. We follow the set representation in this entry. If the domain is $\mathbb{Z}^2$ it is referred to as discrete binary image.

Basic MM Operators on Binary Images

The following are the basic operators from mathematical morphology adapted to binary images.

1. *Dilation*: Given a binary image X and a structuring element B , the dilation is defined as

$$\delta_B(X) = \bigcup_{b \in B} X_b = \bigcup_{x \in X} B_x \quad (1)$$

where X_b denotes the set X translated by b .

2. *Erosion*: Given a binary image X and a structuring element B the erosion is defined as

$$\varepsilon_B(X) = \bigcap_{b \in \hat{B}} X_b \quad (2)$$

where $\hat{B}$ denotes the reflection of B and X_b denotes the translation of X by b .

3. *Opening*: Given a binary image X and a structuring element B the opening is defined as

$$\gamma_B(X) = \delta_B \circ \varepsilon_B(X) \quad (3)$$

4. *Closing*: Given a binary image X and a structuring element B the closing is defined as

$$\phi_B(X) = \varepsilon_B \circ \delta_B(X) \quad (4)$$

Filtering on Binary Images

A morphological filter on a binary image is any operator that is increasing and idempotent and can be obtained by basic dilation/erosion combinations. The opening/closing operators above form the basic filters. Several families of filters can be constructed from these operators such as:

1. *Granulometries*: The idea of a granulometry is similar to filtering out particle based on their sizes. Using the opening operator we can define it as

$$\text{Granulometry} = \gamma_{nB} \circ \gamma_{(n-1)B} \circ \dots \circ \gamma_{2B} \circ \gamma_B \quad (5)$$

Not all structuring elements B are allowed. Usually only disk and line-segments are considered.

2. *Alternating Sequential Filters*: For binary images where noise is spread across different scales and contains both bright and dark distortions, using alternate sequences of opening and closing would help.

$$\text{ASF} = \phi_{nB} \circ \gamma_{nB} \circ \phi_{(n-1)B} \circ \gamma_{(n-1)B} \circ \dots \circ \phi_B \circ \gamma_B \quad (6)$$

One can also start with closing instead of opening as in the above definition.

On the other hand one can define an *algebraic filter*, which is any operator that is increasing and idempotent. Examples of algebraic filters include Area Opening, Attribute Openings, Annular Opening, Convex Hull Closing, etc.

Other Operators on Binary Images

A host of operators can be defined on binary images. A few are stated as follows:

1. *Geodesic Dilation/Erosion*: The geodesic operations force the output to belong to a mask Y . A single step of geodesic dilation is defined as

$$\text{Geo} - \text{Dilate}^{(1)}(X) = \delta_B(X) \cap Y \quad (7)$$

One can suitably define geodesic erosion as well. These operators can be repeated to obtain higher order dilations or erosions.

2. *Hit or Miss Transform (HMT)*: Defined on discrete binary images, these operators extract certain neighborhood configurations in the binary image.
3. *Thinning/Thickening*: Using the HMT transform above, one can obtain the thinning by removing the identified neighborhoods from the existing image and thickening by adding the identified neighborhoods to the existing image.
4. *Skeletonization* involves reducing the binary image to a one-dimensional caricature to extract the most discerning features in the image.

Summary

In this entry, elementary MM operators on binary images, i.e., binary dilation, binary erosion, binary opening, and binary closing are defined. Using these elementary operators, more

complex operators, namely, granulometries, alternating sequential filters, geodesic dilation/erosion, hit or miss transform, thinning/thickening, and skeletonization are then described and intuitively explained.

Definition

A binary partition tree (BPT) is a hierarchy, used to represent a set of regions in a grey-scale image. This hierarchy is constructed using the homogeneity between the regions. The leaf nodes represent the basic regions and the other nodes represent the regions obtained by merging pairs of neighboring regions. The root represents the entire image. See Salembier and Garrido (2000) for more details.

Illustration

To illustrate the definition, consider the image on the left of Fig. 1. This image consists of five regions with the grey-scale value as denoted in the brackets. The corresponding binary partition tree is shown on the right.

To construct the binary partition tree, one starts with merging the neighboring regions with highest affinity. In this case, we have regions A and B which have the highest affinity with respect to their grey-scale values. Hence these regions are merged. The value for combined region is taken to be the average of regional values. So, node AB is assumed to have the value $0.5(75 + 60) = 67.5$. The next closest pair is that of (C, D) . Accordingly, node CD is given the value 20. Then we have that node CD is closer to node AB than node E . Hence, nodes (AB, CD) are combined to get node $ABCD$. Finally region E is merged to obtain the region $ABCDE$.

Construction and Processing the BPT

In the simple example illustrated in Fig. 1 we use the average of grey-scale values. In general the construction of binary partition tree requires the input of two functions -

1. Merging Order: A function which indicates how close the two regions are. In the simple case of Fig. 1 we used the difference between grey-scale values. This can be a more complicated function. See Garrido et al. (1998) for some examples and comparisons.
2. Region Model: One also needs the function which dictates the value of regions which are merged. In Fig. 1 we used the average. However, one might consider taking the weighted average or any other intricate function.

After the BPT is constructed, one can process this to obtain efficient partitions. For instance one can use metrics such as PSNR (peak signal to noise ratio) to cut the hierarchy and obtain suitable partitions. Further, BPT also encodes the spatial relationships between existing objects.

BPT in Edge-Weighted Graphs

BPT can also be defined on edge-weighted graphs. Recall that an edge-weighted graph G is a tuple (V, E, W) where V denotes the vertices, E denotes the edges which is a subset of $V \times V$ and W denotes the edge-weight assigned to each edge in E . Then using the minimum spanning tree construction, one can construct the BPT with altitude as described in Najman et al. (2013). A fast library for implementing BPT on edge-weighted graphs can be found in Perret et al. (2019).

Binary Partition Tree,**Fig. 1** Figure illustrating the binary partition tree**Summary**

In this chapter, a binary partition tree is described as a tool used for hierarchical segmentation of grey-scale images. It is illustrated with the help of a toy example as to how it works. Two types of constructing a BPT are outlined, namely, merging-order based model and region model. Then, a generalization of BPT suited to edge-weighted graphs is briefly mentioned.

Biography

Graeme Bonham-Carter is a mathematical geologist who is known for his research in simulation modeling and geospatial analysis. Graeme was born in England in 1939. He obtained a BA in Natural Sciences and Geology, Cambridge University in 1962, an MA in Geology (1963), and a Ph.D. in Geology (1966) at the University of Toronto followed by a postdoctoral fellowship at Stanford University

from 1966 to 1969. He taught at University of Rochester from 1969 to 1975. He was a research scientist at the Geological Survey of Canada (GSC) from 1980 to 2006. Since retiring he consulted for Canadian Mining Industry Research Organization (CAMIRO), for GSC, and for mineral exploration companies.

While at Stanford, Graeme developed a simulation model of deltas, and published a textbook on computer simulation (Harbaugh and Bonham-Carter 1970). At University of Rochester, he modeled wind-driven circulation of lakes (Bonham-Carter and Thomas 1973). At GSC in Ottawa, he worked on early applications of GIS in geology. With Frits Agterberg he developed the Weights of Evidence (WoE) methodology that was widely adopted for use in mineral prospectivity modeling. In 1994 he published *Geographic Information Systems for Geoscientists: Modelling with GIS* (Bonham-Carter 1994). He led a series of *Mineral Potential Mapping with GIS* short courses that were given first in Canada, then with Gary Raines from USGS in the USA, Australia, and Brazil (Kemp et al. 1999). His interests have included modeling of dispersal of metals around smelters (Bonham-Carter et al. 2006), distribution of metals using selective leaches (Bonham-Carter and Hall 2010), and analysis of portable XRF data (Hall et al. 2014).

Graeme was awarded the 1998 William Christian Krumbein Medal by the IAMG. In 1996 he succeeded Daniel Merriam as Editor-in-Chief of the IAMG journal *Computers & Geosciences (C&G)*, an IAMG journal. In 2008, Graeme co-edited the book *Progress in Geomathematics*, a Festschrift in honor of Frits Agterberg (Bonham-Carter and Cheng 2008). He served as President of the IAMG 2000–2004.

Bootstrap

Oktay Erten and Clayton V. Deutsch
Centre for Computational Geostatistics, University of
Alberta, Edmonton, AB, Canada

Definition

The *bootstrap* is a resampling technique that is used to make inferences about a sampling distribution of a statistic. Its application becomes relevant when there are a few *independent and identically distributed* (iid) observations ($n \leq 25$) which are representative of the *population* for inference. Considering a small *sample* of n observations, the bootstrap randomly samples n observations with replacement, resulting in *resamples* (or bootstrap samples). A statistic of interest is calculated from each resample, and the pooled set of calculated statistics form a *bootstrap distribution*. The *confidence* in the true value of the statistic can be quantified from the bootstrap distribution.

Introduction

In many geoscience applications (i.e., mining, hydrogeology, petroleum, soil science, meteorology, and climatology), there may be only a small sample (tens of observations) available due to the cost of sampling. Spatial modeling of an attribute, conditioned on a few observations, leads to substantial uncertainty associated with the value of the attribute at an unsampled location. Geostatistics provides established techniques to quantify this uncertainty (Pyrz and Deutsch 2014); however, one should also consider that the estimated model parameters (i.e., distribution functions and variograms/covariances) themselves are also uncertain due to the small sample size. Therefore, the uncertainty in model parameters should be quantified and incorporated into attribute modeling.

The traditional bootstrap (Efron and Tibshirani 1993) is a Monte Carlo resampling algorithm used to assess the uncertainty in estimated statistics (i.e., mean, median, and variance) by sampling the empirical data with replacement. In the traditional bootstrap, the sample, deemed representative of the underlying population, is assumed to be composed of iid observations. In other words, the traditional bootstrap does

not consider the spatial correlation between the observations. However, in many geoscience applications, the sampling locations are determined based on a specific sampling strategy, and the attribute has spatial correlation at distances larger than the sample spacing; therefore, the observations cannot be considered independent. Solow (1985) proposed a simulation methodology with LU decomposition of a covariance matrix for obtaining resamples from the spatially correlated observations. A number of studies have also been presented in the literature, which extends the traditional bootstrap procedure to the spatial context (Deutsch 2004; Feyen and Caers 2006; Journel and Bitanov 2004; Olea and Pardo-Igúzquiza 2011). The difference between the traditional and spatial bootstrap is that the latter takes into account the covariance function describing the spatial correlation between the observations.

One of the useful applications of the traditional bootstrap is the quantification of variability in the estimated slope $\hat{\beta}_0$ and intercept $\hat{\beta}_1$ coefficients in a regression model $y_i \approx \hat{\beta}_0 + \hat{\beta}_1 x_i$ for $i = 1, \dots, n$. The residuals $e_i = y_i - \hat{y}_i$ are randomly sampled with replacement, and the resample is generated by using the same x_i value, but with y_i^* obtained from $y_i^* = \hat{y}_i + e_i^*$. As for the spatial bootstrap, the popular application is the assessment of uncertainty in the distribution and the experimental variogram of a spatial attribute. Pardo-Igúzquiza and Olea (2012) proposed a computer program through which the spatially correlated observations $\{z(\mathbf{u}_i), i = 1, \dots, n\}$ are sampled with replacement, and the experimental variogram $\{\hat{\gamma}_j^*(\mathbf{h}), j = 1, \dots, m\}$ is computed for each resample $\{z_j^*(\mathbf{u}_i), i = 1, \dots, n; j = 1, \dots, m\}$. The uncertainty in the experimental variogram $\hat{\gamma}(\mathbf{h})$ of the attribute z is quantified from the bootstrap distribution of each lag estimate. Erten et al. (2020) proposed a methodology for assessing the uncertainty in the experimental variogram considering the nonstationary case. In their methodology, they first estimate the drift model with its uncertainty; they then generate a number of likely drift models using maximum likelihood estimation. The residuals are calculated for each drift model. Each residual set is randomly sampled with replacement, and the resamples from each residual set are combined according to the probability assigned to the corresponding drift models. For each resample, the experimental variogram is computed, and the percentile confidence intervals are calculated for each lag. Khan and Deutsch (2016) extended the spatial bootstrap procedure to the multivariate context by considering the spatial correlation of K attributes sampled at n locations $\{z_k(\mathbf{u}_i), i = 1, \dots, n; k = 1, \dots, K\}$. In their methodology, they first generate m bootstrap realizations of the parameter of interest (mean and variance) for each attribute. They then use each bootstrap realization as a reference distribution to normal score transform the original multivariate sample. The cosimulation of the normal scored attributes is performed, and the final back-transformation of the realizations is carried out with m transform tables. A review of the traditional and

spatial bootstrap methods is given with examples in the next two sections, followed by a discussion section explaining how the domain limits can be considered in the spatial bootstrap procedure. Finally, the summary and conclusion section is presented.

Traditional Bootstrap Resampling

To make any statistical inference without uncertainty, one needs access to the entire population. However, there is only a relatively small sample available, and the statistic must be estimated from the available sample. Consider a population distribution $F(x)$ and a small sample of n iid observations $\{X_i, i = 1, \dots, n\}$ sampled from $F(x)$. Because $F(x)$ is unknown, any statistic of interest, for example, the mean $\bar{X}$ must be estimated from the sampling distribution $F_X(x)$. The uncertainty in the estimated mean can be calculated by:

$$\text{Var}\{\bar{X}\} = \frac{\sigma_X^2}{n} \quad (1)$$

where σ_X^2 is the variance of the sample and n is the number of observations. It is clear from Eq. 1 that as the number of observations increases, the uncertainty decreases. The traditional bootstrap procedure quantifies the uncertainty in the estimated mean by randomly sampling the available data (n) with replacement; that is, we first generate n uniformly distributed random numbers $\{p_i, i = 1, \dots, n\}$ where p lies in the range $0 \leq p \leq 1$, and the corresponding quantiles $\{X_{i,j}^* = F_X^{-1}(p_{i,j}), i = 1, \dots, n; j = 1, \dots, m\}$ are read from the sampling distribution. This procedure is repeated many times, say $m = 1000$ for a stable distribution. Considering each resample $\{X_{i,j}^*, i = 1, \dots, n; j = 1, \dots, m\}$, some observations may appear multiple times and others may not appear at all due to the randomness of the selection of the observations. The mean $\bar{X}_j^*$ is estimated from each resample, and the distribution of the pooled set of means is referred to as the Monte Carlo approximation to the bootstrap distribution, as presented in Fig. 1. As can be seen from Fig. 1, the expected value $E(X) = \mu$ of the population is 4. The small sample of 30 observations was randomly drawn from this population, and the estimated mean of the sampling distribution is $\bar{X} = 4.81$. The observations were randomly drawn with replacement from the sampling distribution, resulting in the resamples $\{X_{i,j}^*, i = 1, \dots, n = 30; j = 1, \dots, m = 1000\}$, each with varying estimated means ($\bar{X}_1^* = 4.89, \bar{X}_{1000}^* = 3.74$). One can see from Fig. 1 that the average (or theoretical mean) of the bootstrap distribution is equal to the sample mean.

The bootstrap confidence intervals can be constructed from the bootstrap distribution. For example, considering 95% confidence interval, the extreme values corresponding to 5% of the bootstrap distribution ($\alpha = 0.05$) are discarded;

Bootstrap, Fig. 1 Traditional bootstrap procedure for $n = 30$ iid observations

that is, the 2.5% smallest and 2.5% largest values are not considered. Given that the bootstrap distribution presented in Fig. 1 is composed of 1000 means, the 25 smallest mean values and 25 largest mean values should be discarded. Once m estimated means are sorted in ascending order of magnitude, the 95% confidence interval is calculated by:

$$\bar{X}_{(\alpha/2) \cdot m}^* < \mu < \bar{X}_{(1-\alpha/2) \cdot m}^* \quad (2)$$

where μ is the expected value of the underlying population; $\bar{X}_{(\alpha/2) \cdot m}^*$ and $\bar{X}_{(1-\alpha/2) \cdot m}^*$ are the estimated means corresponding to the 25th and 975th ranks, respectively. Provided that the original sample is representative of the population and consists of random observations, the bootstrap samples should yield reliable confidence estimates. Considering the example given in Fig. 1, the 95% confidence (or probability) interval for the expected value of the population is $Prob\{\mu \in [3.64, 6.28]\}$.

Spatial Bootstrap Resampling

Consider that Z is an attribute sampled at n locations $\{z(\mathbf{u}_i), i = 1, \dots, n\}$ and modeled by a second-order stationary random function $Z(\mathbf{u})$. Because the observations are spatially correlated, the uncertainty in the estimated mean $\bar{z}$ cannot be calculated using Eq. 1. Considering the spatial correlation between the observations, the variance in the sample mean is in fact equal to the average covariance between the observations; that is,

$$\bar{C}(n, n) = \frac{\sigma^2}{n_{\text{eff}}} \quad (3)$$

where $\bar{C}(n, n)$ is the average covariance, σ^2 is the population variance which is equal to one in the case of normal scored observations, and n_{eff} is the effective number of observations indicating the spatial degrees of freedom in the distribution of the mean. The spatial bootstrap procedure for a single variable is given in the following steps:

1. Define a representative distribution $F_Z(z)$ of the sample of n correlated observations.
2. Transform the spatial data $\mathbf{z}^T = (z_1, z_2, \dots, z_n)$ into the corresponding normal scores $\mathbf{y}^T = (y_1, y_2, \dots, y_n)$ using the normal score transform $\mathbf{y} = G^{-1}(F(\mathbf{z}))$.
3. Fit an analytical model to the experimental variogram of the normal scores of the data, and infer the covariance model $C(\mathbf{h})$.
4. Calculate the $n \times n$ data-to-data covariance matrix $\mathbf{C}$ from the covariance model $C(\mathbf{h})$.
5. Decompose the covariance matrix $\mathbf{C}$ as the product of lower triangular matrix and upper triangular matrix using the Cholesky factorization; that is, $\mathbf{C} = \mathbf{L} \cdot \mathbf{L}^T$, where $\mathbf{L}$ is an $n \times n$ lower triangular matrix.
6. Simulate the unconditional realization of $\mathbf{y}$; that is, $\mathbf{y} = \mathbf{L} \cdot \mathbf{w}$, where $\mathbf{y}$ is the $n \times 1$ unconditional realization, $\mathbf{L}$ is the $n \times n$ lower triangular matrix, and $\mathbf{w}$ is the $n \times 1$ independent (or uncorrelated) standard Gaussian deviates.
7. Convert the simulated Gaussian values to the corresponding probability values; that is, $\mathbf{p} = \mathbf{G}(\mathbf{y})$, where $\mathbf{p}$ is the $n \times 1$ vector of probability values $[0, 1]$.

Bootstrap, Fig. 2 Spatial bootstrap procedure for $n = 67$ spatially correlated observations

8. Draw $\mathbf{z}^*$ values from the empirical conditional cumulative distribution of $\mathbf{z}$ using the probability values; that is, $\mathbf{z}^* = F_{\mathbf{Z}}^{-1}(\mathbf{p})$.
9. Calculate the statistic of interest from the generated realization $\mathbf{z}^*$.
10. Repeat steps 6–9 for a large number m (at least 1000) of resamples.

The LU simulation method, due to its efficiency, is generally used to generate unconditional realizations of n observations with the correct covariance. It is also noted that the LU decomposition of the covariance matrix is required only once. The example given in Fig. 2 indicates that the Au (g/t) grade is sampled at $n = 67$ locations. One can notice that the high grade zone is located in the upper half of the domain. The cell declustering was applied using 85×85 m grid, and the estimated mean of the declustered sample histogram is 1.02. When compared to the mean of the naïve (equal weighted) histogram (1.36), there is a significant decrease in the mean. The experimental variogram of the normal scores of the empirical Au (g/t) data was computed and fitted to an analytical model. Because the second-order stationary assumption holds, the covariance function was obtained through $C(\mathbf{h}) = C(0) - \gamma(\mathbf{h})$. It can be seen from Fig. 2 that the uncertainty in the mean is much less in the case where the spatial correlation between the observations was not considered (Eq. 1). When taking into account the spatial correlation, n_{eff} (Eq. 3) was calculated to be 28.78 which is much less than the number of observations $n = 67$ in the sample. In both

cases, the means of the bootstrap distributions are rather close to the original sample mean.

Discussion

It can be counterintuitive that the spatial bootstrap uncertainty increases when there is greater correlation between the data, yet those data provide more information on the attribute at unsampled locations. It can also be counterintuitive that the spatial bootstrap uncertainty does not consider domain limits. The uncertainty for a small domain with limits close to the data should be less than for a large domain with vast unsampled regions. The spatial bootstrap provides prior uncertainty in a parameter, that is, before conditioning to the data and considering domain limits. The spatial bootstrap parameters used in subsequent spatial modeling are updated by the conditioning data and the domain limits to provide a posterior uncertainty.

Summary and Conclusions

The use of bootstrap resampling technique provides a practical way of accounting for the uncertainty in the global model parameters (i.e., covariance functions, distribution functions) in many geoscience applications. There are two assumptions to consider in the bootstrap procedure: (1) The sample is representative of the underlying population, and (2) the

sample consists of iid observations. The second assumption is violated in the case of spatial samples; therefore, the covariance function describing the spatial correlation between the observations should be taken into account when bootstrapping the spatially correlated observations. Considering the case where there is only a small sample available for spatial modeling of the attribute of interest, neglecting the uncertainty in the model parameters may lead to a bias in the final attribute model.

Two examples show how the bootstrap distributions of the estimated statistic of interest can be constructed through both traditional and spatial bootstrap procedures. In both cases, the bootstrap distributions are normally distributed with a mean equal to approximately the sample mean and a variance calculated through Eqs. 1 and 3, respectively. The percentile confidence intervals can be calculated from the bootstrap distributions, which assess the uncertainty in the estimated statistic. It has also been shown through the second example that in the case of spatial correlation, the uncertainty in the model parameters is expected to be larger than that of the independence case. This is due to the fact that the effective number of observations (n_{eff}) (or number of independent observations) is reduced due to the spatial correlation. The reduced n_{eff} indicates the redundancy between the observations considering the spatial correlation.

Burrough, Peter Alan

Andrew U. Frank

Geoinformation, Technical University, Vienna, Austria

Biography

Peter Burrough was born in Wimborne (England) in 1944 and died in Leiden (Netherlands) 2009. He studied chemistry at the University of Sussex (Brighton) and obtained a Bachelor of Science there in 1965. When he started his doctoral studies at the University of Oxford, he switched to soil sciences; he obtained his doctorate in 1969 with a thesis on “Studies of Soil Survey Methodology.” In the first years he worked on soil surveys in Malaysia but returned to academe for teaching and research and was eventually appointed Professor of Physical Geography and Geographical Information Systems at the Geographical Institute of Utrecht University in 1984.

Peter Burrough was a gifted and productive researcher, picking up new ideas, often from other disciplines and adapted them to geoscience. In 1981 he published an article in *Nature* “Fractal dimensions of landscapes and other environmental data” a subject introduced by Mandelbrot only a few years earlier. Goodchild (2009) summarized the contribution as: “it is the deviations from self-similarity that provide insights into the nature of geographic phenomena.”

Burrough saw early on the contribution computers can make to the practice of geoscience; he looked beyond automated cartography and saw the potential for analyzing geoscientific data. He had the broad academic background to blend different scientific disciplines and bring them to bear on geoscientific topics.

Peter Burrough is probably best known for his book *Principles of Geographical Information Systems for Land Resources Assessment* published in 1986 (Burrough 1986). It was the first comprehensive book on the then novel subject; it went through various editions and is still a widely used text book.

The contribution of this book, however, was beyond just to be the first text book; it showed the importance of geographic information science as a tool and as a science; it demonstrated how scientific principles from mathematics, geometry, and

statistics can be applied to geoscientific topics to yield new insights, helpful for the then emerging environmental sciences.

When affordable computers became powerful enough, Burrough expanded with his graduate students the, then common, static “map algebra” (Tomlin 1990) to a **dynamic** “PC Raster” system (Wesseling et al. 1996) which visualized dynamic environmental processes in space and time described by partial differential equations.

Peter Burrough was always aware of the errors in geoscientific data and the influence of such errors on results and produced with his graduate students a software to explore the effects (Heuvelink 2007). He co-organized a workshop on geographic objects with indeterminate boundaries (Burrough and Frank 1996) which tried to bridge the gap in understanding the influence of uncertainty and error in spatial data in physical and social science data.

Peter Burrough was an inspiring teacher and a mentor for many graduate students, many of whom became successful

researchers and university professors themselves, continuing Burrough’s scientific contributions.

Definition

Cartograms are thematic maps in which the sizes of geographic objects appear in proportion to a quantitative mapping variable. There are two types of cartograms. If the mapping variable is represented by the areas of the depicted regions, the map is called an *area cartogram*. If distances between points are a substitute for the mapping variable, the map is called a *distance cartogram*. Both cartogram types visualize quantitative data by distorting familiar geographic features. However, area cartograms and distance cartograms have distinct applications, and their construction requires different mathematical and algorithmic techniques. Suitable mapping variables for area cartograms are quantities that can be associated with nonoverlapping regions on a map (e.g., countries or provinces). Area cartograms are frequently used in human geography to visualize population distributions (“isodemographic maps”) or economic indicators (e.g., gross domestic product). Distance cartograms usually represent travel times (“time-space maps”), but other measures of separation (e.g., travel costs or fuel consumption) can also be used.

Area Cartogram

The mathematical objective of an area cartogram (also known as “value-by-area map”) is to transform geographic regions, given in the form of multipolygons, into new multipolygons with areas that match quantitative data associated with each region. The output should maintain certain properties of conventional geographic maps (e.g., the locations and shapes of regions) and maintain the regions’ topology (i.e., regions should share a common border on the cartogram if and only if they share a common border in geographic space). It is generally impossible to achieve all these objectives simultaneously. A variety of area cartogram types have been developed that relax different constraints. The main categories of area cartograms are rectangular cartograms, mosaic cartograms, circular cartograms, noncontiguous cartograms, and contiguous cartograms (Fig. 1). For a review of area cartograms, including further cartogram types, see Tobler (2004), and Nusrat and Kobourov (2016).

Rectangular Cartograms

In a rectangular cartogram, each region is represented by a rectangle with an area equal to a numeric input (Fig. 1a). Rectangular cartograms are the oldest cartogram type with hand-drawn examples dating back to the late nineteenth century (see Tobler 2004 for a historical account). Maintaining the correct adjacency of regions is generally impossible in rectangular cartograms. Algorithms have been created to automate the construction of rectangular cartograms with correct topology, but only after landlocked regions with fewer than four neighbors are manually merged with one of the surrounding regions (Buchin et al. 2012). A variation of the rectangular cartogram with fewer topological constraints is the rectilinear cartogram, in which each region can be composed of multiple rectangles.

Cartogram, Fig. 1 Area cartograms. (a) Rectangular cartogram depicting the population of Europe (Buchin et al. 2012). (b) Mosaic cartogram for the same data (Cano et al. 2015). (c) Circular cartogram illustrating the predicted world population in 2030 (Inoue 2011). (d) Noncontiguous cartogram representing the 2005 population of African

countries (Jeworutzki 2020). (e) Contiguous cartogram for the 2016 US presidential election. The area of each state in the cartogram is proportional to the number of electors. Red states were won by Republicans, blue states by Democrats (Gastner et al. 2018)

Mosaic Cartograms

Mosaic cartograms divide the map into a set of small square-shaped or hexagonal tiles, each of equal size and orientation (Fig. 1b). The most suitable thematic mapping variables for

mosaic cartograms are those that take small integer values so that one tile corresponds to one discrete unit (e.g., a seat in parliament). Tiles are assigned to regions such that contiguous geographic regions are represented by contiguous sets of tiles.

For some data, topological errors are inevitable because the details of real geographic boundaries cannot be represented by the discrete shapes of the tiles. To minimize the topological errors, Dorling (1996) developed a cellular automaton algorithm for the construction of mosaic cartograms. A recently proposed algorithm aims to improve the preservation of the regions' shapes (Cano et al. 2015).

Circular Cartograms

Circular cartograms represent each region by a circle with an area that is proportional to the thematic mapping variable (Fig. 1c). Circles are placed such that they may touch, but do not overlap. Dorling's (1996) circular cartogram algorithm and a recent refinement by Inoue (2011) aim to place the centers of the circles approximately at the same position where the region centroids would be on a conventional map. Unlike rectilinear and mosaic cartograms, circular cartograms always leave unfilled space in the interior of the map. The restriction to circular shapes may also force neighboring geographic regions to appear separated on the cartogram.

Noncontiguous Cartograms

Noncontiguous cartograms deliberately introduce empty space between the depicted regions (Fig. 1d) and, thus, make no attempt to represent the topological relations between the regions. The empty space between polygons allows noncontiguous cartograms to depict the shapes of the regions accurately. Olson (1976) described a construction method for noncontiguous cartograms, in which each polygon is shrunk isotropically towards its centroid. The method tends to create excessive empty space between the polygons. It can also lead to region overlaps if polygons are concave or contain holes. A fully automated fail-safe algorithm has yet to be described in the literature. Hence, the construction of noncontiguous cartograms currently relies on manual adjustments with image editing software.

Contiguous Cartograms

Contiguous cartograms correctly represent common borders and tripoints between the depicted regions (Fig. 1e). Construction methods for contiguous cartograms can be divided into two distinct classes. The first class ("boundaries-only" methods) restricts itself to moving a finite number of boundary points from their geographic position (e.g., given as latitude and longitude) to their positions on a cartogram. The second class creates a cartogram by establishing a "density-equalizing map projection" that shifts every point in continuous geographic space to a new position, regardless of whether the point is on a boundary.

Boundaries-only algorithms can influence the polygon shapes more directly than algorithms that involve continuous map projections. Consequently, several boundaries-only algorithms explicitly seek a compromise between

maintaining polygon shapes and achieving correct polygon areas (House and Kocmoud 1998; Keim et al. 2004). A disadvantage of the boundaries-only approach is that it does not attribute any semantics to points that are not on a boundary. By contrast, a density-equalizing map projection makes it possible to show additional data that are resolved at a finer level than the polygons to be displayed (e.g., addresses, roads, or distributions on a fine-grained grid; see Hennig 2013).

A density-equalizing map projection is a two-dimensional function $\mathbf{T} = (T_x; T_y)$ that satisfies

$$\det J_{\mathbf{T}} \equiv \frac{\partial T_x}{\partial x} \frac{\partial T_y}{\partial y} - \frac{\partial T_y}{\partial x} \frac{\partial T_x}{\partial y} = \frac{\rho(x, y)}{\bar{\rho}} \quad (1)$$

where $\det J_{\mathbf{T}}$ is the Jacobian determinant of $\mathbf{T}$, (x, y) are coordinates on an equal-area projection, $\rho(x, y)$ is the local density of the mapping variable (e.g., population per square kilometer), and $\bar{\rho}$ is the spatial average. Equation (1) does not uniquely specify a projection. Various additional constraints have been proposed to determine a unique solution. Tobler (1973) suggested selecting the most angle-preserving projection among all solutions to Eq. (1). In practice, Tobler's optimization algorithm failed to converge. However, several alternatives, based on analogies from physics, have led to satisfactory results (Gusein-Zade and Tikunov 1993; Sun 2020). The technique by Gastner et al. (2018) treats $\rho(x, y)$ as the density of a fluid that equilibrates over time. This method solves Eq. (1) by calculating a vortex-free and mass-conserving velocity field. The calculation, performed with fast Fourier transforms, has been implemented as a web application (<https://go-cart.io/>; see Tingsheng et al. 2019).

Distance Cartogram

The objective of a distance cartogram (also called "linear cartogram") is to place a set of points in a flat two-dimensional geometric space such that the distances between the points are proportional to a quantitative measure of separation. Hereinafter, we assume that the measure of separation is travel time, which is by far the most frequently used mapping variable for distance cartograms.

There are two broad categories of distance cartograms. In the first category ("central-point cartogram"), only travel times from a central location are represented on the cartogram (Fig. 2a). The second category ("network cartograms") aims to represent travel times in a network whose links are not necessarily connected to a unique central node (Fig. 2b).

The construction of central-point cartograms is straightforward. Points can be placed at a distance that is strictly proportional to the travel time, and the angle of the connecting line to the central point can be chosen arbitrarily (e.g., to

Cartogram, Fig. 2 Distance cartograms. (a) Central-point cartogram showing the travel time from Tokyo by train in 1965. (b) Network cartogram based on pairwise travel times between 81 Japanese cities. (Figure from Shimizu and Inoue (2009))

match the angle on a conventional map). Network cartograms pose greater challenges because it is generally impossible to simultaneously satisfy the distance constraints for all point pairs. Instead, the aim is to minimize the deviation from proportionality. A common objective function is

$$\min f(x_1, \dots, x_n, y_1, \dots, y_n) = \sum_{(i,j) \in L} \left(t_{ij} - \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \right)^2 \quad (2)$$

where x_i and y_i are the coordinates of point i on the cartogram, and t_{ij} is the travel time from i to j . L is the set of all links whose travel times are to be visualized. Minimizing f is equivalent to multidimensional scaling, a common mathematical technique for dimension reduction in statistics. The solution to Eq. (2) is not unique because any rotation and translation leaves f unchanged. To select a unique solution, it is sensible to conduct the following post-hoc steps (Ewing and Wolfe 1977):

- Scale the cartogram coordinates such that the mean of all distances between pairs of points matches the mean interpoint distance in physical space.
- Shift the cartogram coordinates such that the centroid of the points on the cartogram is the same as the centroid of their physical locations.
- Rotate the cartogram coordinates around the centroid such that the rotated coordinates minimize the sum of the squared distances from the physical coordinates.

If L contains all $n(n-1)/2$ possible links between n points, good numerical results were obtained using the technique described above (Marchand 1973). However, if some point pairs are missing from L , there can be multiple solutions to Eq. (2) which differ by more than an overall rotation and translation. In this case, the algorithm should aim to minimize angular distortion to produce readable cartograms (Shimizu and Inoue 2009).

It is often informative to show more than the transformed network locations $(x_1, y_1), \dots, (x_n, y_n)$ on the cartogram. For example, coastlines and administrative boundaries can add valuable context. In this case, the transformation from the physical locations $(x_i^p, y_i^p), i \in \{1, \dots, n\}$ to the cartogram locations (x_i, y_i) must be spread into a continuous two-dimensional space. Ideally, this task is achieved by a continuous map projection $\mathbf{T}$ that interpolates smoothly between the n points in the network such that $\mathbf{T}(x_i^p, y_i^p) = (x_i, y_i)$. However, standard interpolation methods can result in graticule cells whose winding orientation is locally inverted. That is, there can be coordinates (x, y) where the Jacobian determinant $\det J_{\mathbf{T}}(x, y)$ is negative, especially where fast long-distance connections are geographically close to slow short-distance connections. To alleviate this problem, Spiekermann and Wegener (1994) proposed a modification of multidimensional scaling, called “stepwise multidimensional scaling.” However, a rigorous proof that this method avoids local inversions in $\mathbf{T}$ remains an open research challenge.

Summary

Conventionally, geographic maps are designed to faithfully represent metric properties such as areas, distances, or angles. Cartograms offer an alternative map design with the primary aim of visualizing quantitative statistical data instead of geometric properties. Data associated with nonoverlapping two-dimensional regions can be shown on area cartograms, for which many different designs have been developed over the past decades. Data that quantify the degree of separation between points (e.g., travel time) can be visualized with distance cartograms. Although both types of cartograms appear inevitably distorted, they can be effective alternatives to traditional thematic maps (e.g., choropleth maps or proportional-symbol maps).

Chaos in Geosciences

Frits Agterberg¹ and Qiuming Cheng²

¹Central Canada Division, Geomathematics Section, Geological Survey of Canada, Ottawa, ON, Canada

²State Key Lab of Geological Processes and Mineral Resources, China University of Geosciences, Beijing, China

Definition

Randomness is widespread in the sciences including geoscience. The concepts of probability and random deviations from an average value have been known to exist since the sixteenth century (Hacking 2006). During the second part of the twentieth century, it was found that various random variables could be modeled as fractals or multifractals. It was also discovered that nonlinear differential equations can result in varied forms of chaos closely linked to fractals or multifractals. According to Turcotte (1997), the introduction of the concept of chaos stems from the original work by Lorenz (1963) who employed nonlinear equations to describe thermal convection in a fluid. Although his equations were deterministic, they resulted in a chaotic solution. Infinitesimal variations in initial conditions led to unpredictable differences in the outcome. Later, Motter and Campbell (2013) showed that the Lorenz attractor has a fractal dimension.

May (1976) introduced the logistic map to represent population dynamics of animal species with an annual breeding cycle. Schuster (1995) and Turcotte (1997) explain May's logistic map model in detail and present other examples of deterministic chaos. Bak (1996) introduced a new theory of complex systems using geoscience examples including his sandpile model for avalanche sizes that satisfies Zipf's (1949) law for fractals describing a straight line relationship on log-log plots. Sagar et al. (2003) expanded Bak's approach by simulating avalanches in sand dune formation experiments.

Introduction

A question to which new answers are being sought is: Where does the randomness in Nature come from? Nonlinear process modeling is providing new clues to answer this question. Deterministic models can produce chaotic results with fractal properties. A famous early example was described in Poincaré's (1899) study of the three-body problem in mechanics. This author observed that in some systems it may happen that small differences in the initial conditions produce very great ones in the final phenomena, and "... prediction becomes impossible." Nevertheless, the randomness created by nonlinear processes obeys its own specific laws. Many scientists including Turcotte (1997) have pointed out that, in chaos theory, otherwise deterministic Earth process models can contain terms that generate purely random responses. Examples include the logistic equation and the van der Pol equation with solutions that contain unstable fixed points or bifurcations.

Multifractals, which are spatially intertwined fractals and were anticipated by Hans de Wijs (1951), provide a novel approach to problem solving in situations where the attributes display strongly positively skewed frequency distributions. The original de Wijs model is discussed in more detail in the entry by S. Xie elsewhere in this Encyclopedia (also see Xie and Bao 2004). Another example of this type will be given later in the current entry. The multifractal method of local singularity mapping uses short-distance variability to delineate places with relatively strong enrichment or depletion of element concentration on geochemical maps and in other applications (Cheng and Agterberg 2009) offering a new approach for mineral exploration and regional environmental assessment. Such nonlinear developments are closely related to statistical theory of extreme events (Beirlant et al. 2005).

Model of de Wijs

A relatively simple multiplicative cascade model in 1-D, 2-D, or 3-D is the model of de Wijs (1951). This model is graphically illustrated in Figs. 1 and 2. In the original model of de Wijs, a block of rock is divided into two equal parts. The concentration value (ξ) of a chemical element in the block can be written as $(1 + d) \times \xi$ for one half and $(1 - d) \times \xi$ for the other half so that total mass is preserved. The coefficient of dispersion d is assumed to be independent of block size. For the first cell at the beginning of the process, ξ can be set equal to unity. This implies that all concentration values are divided by their overall regional average concentration value (μ). The index of dispersion (d) is independent of cell size. In 2-D space, two successive subdivisions into quarters result in 4 and 16 cells with concentration values as shown in Fig. 1.

	$(1+d)$	$(1-d)$		
	$(1+d)^2$	$(1+d)(1-d)$	$(1-d)^2$	
	$(1+d)(1-d)$	$(1-d)^2$		
$(1+d)^4$	$(1+d)^3(1-d)$	$(1+d)^2(1-d)^2$	$(1+d)(1-d)^3$	$(1-d)^4$
$(1+d)^3(1-d)$	$(1+d)^2(1-d)^2$	$(1+d)(1-d)^3$	$(1-d)^4$	
$(1+d)^2(1-d)^2$	$(1+d)(1-d)^3$	$(1-d)^4$		
$(1+d)(1-d)^3$	$(1-d)^4$			
$(1-d)^4$				

Chaos in Geosciences, Fig. 1 First stages of two-dimensional cascade model of de Wijs. Overall mean concentration value was set equal to one; d = dispersion index. Non-Random index matrix corresponds to (4×4) squares distribution of concentration values. (Source: Agterberg 2007, Fig. 2a)

The maximum element concentration value after k subdivisions is $(1 + d)^k$ and the minimum value is $(1 - d)^k$.

The model of de Wijs is a random cascade in which larger and smaller values are assigned to cells using a discrete random variable. Multifractal patterns generated by a random cascade of this type have more than a single maximum. The frequency distribution of the element concentrations at any stage of this process is called "log-binomial" because logarithmically transformed concentration values satisfy the binomial distribution model. The log-binomial converges to a lognormal distribution although its upper and lower value tails do remain weaker than those of the lognormal (Agterberg 2007). Because of its property of self-similarity, the model of de Wijs was recognized to be a multifractal by Mandelbrot (1989), who adopted this approach for various applications to the Earth's crust.

Figure 2 shows a 2-D log binomial pattern for $d = 0.4$ and $k = 14$. Increasing the number of subdivisions for the model of de Wijs (as in Fig. 1) to 14 results in the (128×128) pattern shown where values greater than 4 were truncated to more clearly display most of the spatial variability. The frequency distribution of all values is log-binomial and approximately lognormal except in the highest-value and lowest-value tails that are thinner. When the number of subdivisions becomes large, the end product cannot be distinguished from that of multiplicative cascade models in which the dispersion index D is modeled as a continuous random variable with mathematical expectation equal to 1 instead of the Bernoulli variable allowing the values $+d$ and $-d$ only. The lognormal model often provides good first approximations for regional background distributions of trace elements. The multifractal method used for estimating d is similar to the method for separation of geochemical anomalies from background introduced by Cheng (1994) and Cheng et al. (1994).

The model of de Wijs is a multifractal that satisfies the property of scale-independence. Its multifractal property

Chaos in Geosciences, Fig. 2 Realization of model of de Wijs (see Fig. 1 in 2-D for $d = 0.4$ and $n = 14$). Overall average value is equal to 1. Values greater than 4 were truncated. (Source: Agterberg 2007, Fig. 3)

provides an example of renormalization group models producing fractal statistics explicitly utilizing the principle of scale invariance. Other methods of this type are discussed by Turcotte (1997), who in the last chapter of his book also provides examples of self-organized criticality not only resulting in patterns with fractal properties but basically originating from deterministic differential equations.

Gold in South Saskatchewan till Example

The approach described in the previous section is illustrated by application to gold content of till samples obtained during a systematic ultra-low density (1 site per 800 km²) geochemical reconnaissance survey in southern Saskatchewan (see Fig. 3). There are 389 observed gold concentration values ranging from below detection limit to 77 ppb. All Au values

below detection limit (= 2 ppb) were set equal to 1 ppb. The arithmetic mean gold concentration value is 2.5 ppb. In total, only about one-third of 389 observed values exceed this average. Overall, average gold value of 2.5 ppb slightly overestimates true mean gold concentration value because most gold values below 2 ppb are probably less than 1 ppb.

A lognormal Q - Q plot for Au is shown in Fig. 4 with its line of best fit. Because natural logarithms are used, the standard deviation of logarithmically transformed concentration values can be set equal to the inverse of the slope of the best-fitting straight line. It amounts to 2.37 ppb for Au. Original sampling design for the geochemical reconnaissance study in Southern Saskatchewan is described by Garrett and Thorleifson (1995) who selected an 80 × 80 km grid as the basic sampling cell, which was successively subdivided into 40 × 40 km, 20 × 20 km, and finally 10 × 10 km grid cells for sampling with randomly selected 1 × 1 km target

Chaos in Geosciences, Fig. 3 Study area of 64 cells with locations of till samples, Southern Saskatchewan. Unit of distance for east-west and north-south directions is 78.125 km. (Source: Agterberg 2007, Fig. 9)

Chaos in Geosciences, Fig. 4 Straight line fitted to part of lognormal $Q-Q$ plot for 64 average gold concentration values for cells. (Source: Agterberg 2007, Fig. 10)

cells. Compositional data for many other elements and minerals were determined as well. Gold was selected for this example because its frequency distribution seems to be unimodal, and Au had been used extensively in other multifractal studies (cf. Cheng 1994).

For the case study described here, a modified grid was used for Southern Saskatchewan resulting in a square-shaped study area consisting of 64 square cells measuring slightly less than 80 km on a side (see Fig. 3). The purpose of this redefinition of boundaries of study area was to minimize edge effects in the multifractal analysis. Data from outside the square study area were not used. In total, 290 of the original 389 (on average, about 4.5/cell) were retained. The Au logarithmic variance estimated from the 379 original till samples is 2.369.

de Wijs (1951) derived the following equation for the variance of logarithmically transformed element concentration values:

$$\sigma^2 = \frac{n}{4} (\ln \eta)^2$$

where σ^2 is the logarithmic variance (base e) and $\eta = (1 + d)/(1 - d)$. Application of this equation yields $n = 26.1$. This apparent maximum number of subdivisions of the environment would correspond to square cells measuring approximately 75 m, and 40 m on a side, respectively. Clearly, these cells are much larger than the very small areas where the till was actually sampled for the purpose of chemical analysis. It shows that the regional model of de Wijs for Au does not apply at the local sampling scale.

The log-binomial distribution for gold is shown in the lognormal $Q-Q$ plot of Fig. 5. Because the negative binomial is discrete, the preceding estimate of n was rounded off to the nearest integer. The parameters of the distribution shown are

Chaos in Geosciences, Fig. 5 Lognormal $Q-Q$ plots for discrete binomial frequency distributions of gold concentration values resulting from the model of the Wijs. Overall average Au concentration value $\xi = 1.82$ ppb, dispersion index $d = 0.433$, and apparent number of subdivisions of the environment $n = 26$. (Source: Agterberg 2007, Fig. 13)

$\xi = 1.82$ ppb, $d = 0.433$, and $n = 26$ for gold (Fig. 5). The mean value ξ was determined by forcing the log-binomial and its lognormal approximation through the centers of clusters of points on lognormal Q - Q plots for original data. This result remains approximate but is interesting in that it permits shape comparison of the log-binomial and lognormal tails.

The Lorenz Attractor

It can be argued that nonlinear process modeling originated in 1963 when the meteorologist Edward Lorenz (1963) published the paper entitled “Deterministic nonperiodic flow” (cf. Motter and Campbell 2013). Earlier, he had accidentally discovered how miniscule changes in the initial state of a time series computer simulation experiment grew exponentially with time to yield results that did not resemble one another although the equations controlling the process were the same in all experiments (Lorenz 1963). It turned out that the notion of absolute predictability, although it had been assumed intuitively to hold true in classical physics, is in practice false for most systems. In the title of a talk Lorenz

gave in 1972, he aptly referred to this chaotic behavior as the “butterfly effect” asking if the flap of a butterfly in Brazil could set off a tornado in Texas (Fig. 6).

Lorenz (1963) presented chaos theory by using a three-variable system of nonlinear ordinary differential equations now known as the Lorenz equations. The model derives from a truncated Fourier expansion of the partial differential equations describing a thin, horizontal layer of fluid that is heated from below and cooled from above. The equations can be written as: $dx/dt = a(-x + y)$, $dy/dt = cx - y - xz$, and $dz/dt = -bz + xy$, where x represents intensity of convective motion, y is proportional to the temperature difference between the ascending and descending convective currents, and z indicates the deviation of the vertical temperature profile from linearity. The parameters b and c represent particulars of the flow geometry and rheology. Lorenz set them equal to $b = 8/3$ and $c = 10$, respectively, leaving only the Rayleigh number a to vary. For small c , the system has a stable fixed point at $x = y = z = 0$, corresponding to no convection. If $24.74 > c \geq 1$, the system has two symmetrical fixed points, representing two steady convective states. At $c = 24.74$, these two convective states lose stability; at $c = 28$, the system

Chaos in Geosciences, Fig. 6 The Lorenz attractor as revealed by the never-repeating trajectory of a single chaotic orbit (Motter and Campbell 2013). The spheres represent iterations of the Lorenz equations, calculated using the parameters originally used by Lorenz (1963). Spheres are

colored according to iteration count. The two lobes of the attractor resemble a butterfly, a coincidence that helped earn sensitive dependence on initial conditions. Hence, its nickname: “the butterfly effect.” (Source: Agterberg 2014, Fig. 12.9)

shows nonperiodic trajectories. Such trajectories orbit along a bounded region of 3-D space known as a chaotic attractor, never intersecting themselves (Fig. 6). For larger values of c , the Lorenz equations exhibit different behaviors that have been catalogued by Sparrow (1982).

Conceptionally, chaos is closely connected to fractals and multifractals. The attractor's geometry can be related to its fractal properties. For example, although Lorenz could not resolve this particular problem, his attractor has fractal dimension equal to approximately 2.06 (Motter and Campbell 2013, p. 30). An excellent introduction to chaos theory and its relation to fractals can be found in Turcotte (1997). The simplest nonlinear single differential equation illustrating some aspects of chaotic behavior is the logistic equation that can be written as $dx/dt = x(1 - x)$ where x and t are non-dimensional variables for population size and time, respectively. There are no parameters in this equation because characteristic time and representative population size were defined and used. The solution of this logistic equation has fixed points at $x = 0$ and 1, respectively. The fixed point at $x = 0$ is unstable in that solutions in its immediate vicinity diverge away from it. On the other hand, the fixed point at $x = 1$ has solutions in its immediate vicinity that are stable. Introducing the new variable, $x_1 = x - 1$, and neglecting the quadratic term, the logistic equation has the solution $x_1 = x_{10} \cdot e^{-t}$ where x_{10} is assumed to be small but constant. All such solutions "flow" toward $x = 1$ in time. They are not chaotic.

Chaotic solutions evolve in time with exponential sensitivity to the initial conditions. The so-called logistic map arises from the recursive relation $x_{k+1} = a \cdot x_k (1 - x_k)$ with iterations for $k = 0, 1, \dots$. May (1976) found that the resulting iterations have a remarkable range of behavior depending on the value of the constant a that is chosen. Turcotte (1997, Sect. 10.1) discusses in detail that there now are two fixed points at $x = 0$ and $1 - a^{-1}$, respectively. The fixed point at $x = 0$ is stable for $0 < a < 1$ and unstable for $a > 1$. The other fixed point is unstable for $0 < a < 1$, stable for $1 < a < 3$, and unstable for $a > 3$. At $a = 3$ a so-called flip bifurcation occurs. Both singular points are unstable and the iteration converges on an oscillating limit cycle. At $a = 3.449479$, another flip bifurcation occurs and there suddenly are four limit cycles. The approach can be generalized by defining successive constants a_i ($i = 1, 2, \dots, \infty$) leading to limit cycles that satisfy the iterative relation $a_{i+1} - a_i = F^{-1} (a_i - a_{i-1})$ where $F = 4.669202$ is the so-called Feigenbaum constant. Turcotte (1997, Figs. 10.1–10.6) shows examples of this approach. Sornette et al. (1991) and Dubois and Cheminée (1991) have treated the eruptions of the Piton de la Fournaise on Réunion Island and Mauna Lao and Kilauea in Hawaii using this generalized logistic model.

The preceding examples of deterministic processes result in chaotic results. However, one can ask the question of whether there exist deterministic processes that can fully explain fractals and multifractals? The power-law models related to fractals and multifractals can be partially explained on the basis of the concept of self-similarity. Various chaotic patterns observed for element concentration values in rocks and orebodies could be partially explained as the results of multiplicative cascade models such as the model of de Wijs. These models invoke random elements such as increases of element concentration that are not deterministic.

Successful applications of nonlinear modeling in geoscience also include the following: Rundle et al. (2003) showed that the Gutenberg-Richter frequency-magnitude relation is a combined effect of the geometrical (fractal) structure of fault networks and the nonlinear dynamics of seismicity. Most weather-related processes taking place in the atmosphere, including cloud formation and rainfall, are multifractal (Lovejoy and Schertzer 2007). Other space-related nonlinear processes include "current disruption" and "magnetic reconnection" scenarios (Uritsky et al. 2008). Within the solid Earth's crust, processes involving the release of large amounts of energy over very short intervals of time including earthquakes (Turcotte 1997), landslides (Park and Chi 2008), flooding (Gupta et al. 2007), and forest fires (Malamud et al. 1998) are nonlinear and result in fractals or multifractals.

Summary and Conclusions

Nonlinear process modeling is providing new clues to answers of where the randomness in nature comes from. From chaos theory it is known that otherwise deterministic Earth process models can contain terms that generate purely random responses. The solutions of such equations may contain unstable fixed points or bifurcations. It was shown that multifractals provide a novel way of approach to problem solving in situations where the attributes display strongly positively skewed frequency distributions. Randomness in the geosciences has been known to exist since the sixteenth century but it is only fairly recently that chaos theoretical explanations using deterministic differential equations are being developed. The results of chaos theory often are shown to possess fractal or multifractal properties. The model of de Wijs applied to gold concentration values in till was used as an example in this entry. It can be assumed that future developments of chaos theory will help to explain various forms of randomness and multifractals in the geosciences.

Chayes, Felix

Richard J. Howarth
Department of Earth Sciences, University College London
(UCL), London, UK

Fig. 1 Felix Chayes in 1970. (Reproduced with permission of the Geophysical Laboratory, Carnegie Institution of Washington)

Biography

The quantitative petrographer (Charles) Felix Chayes was born in New York City, on 10 May 1916. He majored in geology at New York University (BA 1936), then moved to Columbia University, NY, to study the alkaline intrusives of Bancroft, Ontario, Canada (MA 1939; PhD 1942). Joining the US Bureau of Mines in 1942, he introduced grain-fragment counting to monitor the composition of quarried granite products.

In 1947 he joined the Geophysical Laboratory, Carnegie Institution, Washington, DC, and studied the compositional variation of fine-grained New England granites, using “modal analysis” (i.e., “point-counting” the proportions of mineral

grains in a thin-section; Chayes 1956) and undertook similar investigations elsewhere. Advised by statisticians Joseph Cameron (1922–2000) and William Youden (1900–1971) from the National Bureau of Standards (NBS), Washington, he tried to alert geologists to problems posed by data in which “the sum of the variates is itself a variable . . . [which] is actually, or practically, constant. The effect . . . is to generate negative correlation” (Chayes 1948, p. 415). He introduced the term “closed table” for one having a constant-sum property. Realizing that major-element geochemical data caused similar ratio-correlation problems which affected both petrographic attributes and derived CIPW- and Niggli-normative compositions, he repeatedly drew attention to these difficulties thereafter. Advised by statistician William Kruskal (1919–2005) of the University of Chicago, he developed a test for the significance of such spurious correlations, but it subsequently became apparent that there were problems with it.

In 1961, Spanish petrologist José Luis Brändle began work with Chayes to assemble a database of major-element analyses of Cenozoic volcanic rocks and in 1971, funded by the National Science Foundation, Chayes began to undertake data-retrieval requests. He became Chair of the International Union of Geological Sciences (IUGS) Subcommittee on Electronic Databases for Petrology in 1984.

With the advice of NBS statisticians Cameron, Calyampudi Rao (1920–) and Geoffrey Watson (1921–1998), Chayes and Danielle Velde (1936–; née Métais) were early users of discriminant analysis to distinguish between igneous rock types, based on their major-element chemical compositions (Chayes and Métais 1964), but later work revealed the inherent variability of such procedures when using small numerical sample sizes.

Chayes (1968) also used least-squares mixing-models to estimate the composition of the unexposed “hidden zone” of the Skaergaard layered intrusion, East Greenland.

Chayes and Brändle sought to enlarge their database to include both trace-element and petrographic data. This resulted in the IUGS “IGBADAT” database for igneous petrology and its support software; keeping it updated dominated Chayes’ later years – its fifth release in 1994 contained 19,519 rock analyses. After 1986, he worked part-time at the Geophysical Laboratory and at the National Museum of Natural History, Washington. He died on February 28, 1993, as the result of a car accident.

A Charter Member (1968–1993) of the International Association for Mathematical Geology (IAMG), he was awarded its William Christian Krumbein Medal in 1984. The IAMG’s Felix Chayes Prize for Excellence in Research in Mathematical Petrology was established in his memory in 1997. For more information, see Howarth (2004).

Cheng, Qiuming

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Fig. 1 Qiuming Cheng, courtesy of Prof. Cheng

Biography

Professor Qiuming Cheng was born in 1960 in Taigu County, China. He received a BSc in mathematics (1982) and MSc in mathematical geology (1985) at Changchun University of Earth Sciences where he was appointed Associate Professor. In 1991 he became a PhD student at the University of Ottawa. Within 3 years, he completed his doctoral thesis (Cheng 1994)

recognized by the university as its best doctoral dissertation for that year. The university's citation included the sentence "Dr. Cheng has demonstrated his potential as a world-class scientist, producing results that are important not only in the geosciences but also in physics and mathematics." This prediction was amply fulfilled. After a one-year post-doctorate fellowship at the Geological Survey of Canada in Ottawa, Dr. Cheng was awarded a professorship at York University with cross-appointment in the Department of Earth and Space Science and Department of Geography. In 2004 he also became a Changjiang Scholar in China and Director of the State Key Laboratory of Geological Processes and Mineral Resources (GPMR) which is part of the China University of Geosciences with campuses in Wuhan and Beijing. In 2017 he retired from York in order to perform research and teach fulltime at CUG Beijing. In 2019 he was elected to membership in the Chinese Academy of Sciences.

Professor Cheng's research focuses on the development of mathematical geocomplexity theory for modeling nonlinear geo-processes and quantitative prediction of mineral resources (see e.g., Cheng 2005). His pioneering work on new fractal theory and local singularity analysis (Cheng 2007) has made major impacts on several geoscientific sub-disciplines including those concerned with extreme geological events originated from nonlinear processes of plate tectonics such as the formation of supercontinents, mid-ocean ridge heat flow, earthquakes, and the formation of ore deposits (Cheng 2016). He has authored or co-authored over 300 refereed journal papers or book chapters and delivered over 100 invited papers or keynote lectures. In 1997 he obtained the President's Award of the International Association for Mathematical Geosciences (IAMG) given to scientists aged 35 or less. In 2008, the IAMG awarded him the William Christian Krumbein medal, its highest award for lifetime achievements in mathematical geoscience, service to the profession and contributions to the IAMG of which he became the 2012–2016 President. From 2016 to 2020, Professor Cheng was President of the International Union of Geological Sciences with over a million members in its affiliated organizations.

Circular Error Probability

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Circular error probability applies to the directions of linear features in two-dimensional space that are subject to uncertainty. Statistical analysis of directional data differs from ordinary statistical analysis based on the normal distribution. Linear features are either directed or undirected. For example, paleocurrents can result in features from which it can be seen in which direction the current was flowing or they result in symmetrical features from which the direction of flow cannot be determined. A sample of n features has values that can be written as x_i ($i = 1, 2, \dots, n$). The probability $P(x_i)$ of occurrence of x_i ranges from 0° to 360° (or from 0 to 2π). The system is closed because $x_i \geq 360^\circ = x_i - 360^\circ$. Estimates of average directions are affected by closure if relatively many measurements deviate significantly from the arithmetic mean; e.g., when the standard deviation of the sample significantly exceeds 30° .

Introduction

Various geological attributes may be approximated by lines or planes. Measuring them results in "angular data" consisting of azimuths for lines in the horizontal plane or azimuths and dips for lines in 3D space. Although a plane usually is represented by its strike and dip, it is fully determined by the line perpendicular to it, and statistical analyses of data sets for lines and planes are analogous. Examples of angular data are strike and dip of bedding, banding, and planes of schistosity, cleavage, fractures, or faults. Azimuth readings with or without dip are widely used for sedimentary features such as axes of elongated pebbles, ripple marks, foresets of cross-bedding and indicators of turbidity flow directions (sole markings). Then there are the B-lineations in tectonites. Problems at the microscopic level include that of finding the preferred orientation of crystals in a matrix (e.g., quartz axes in petrofabrics).

Initially, circular data in geoscience were treated like ordinary data not subject to the closure constraint (see, e.g., analysis of variance treatment by Potter and Olson (1954). However, increasingly 2D (and 3D) directional features were treated by methods that incorporated the closure constraint of vectorial data (Watson and Williams 1956; Stephens 1962). However, Agterberg and Briggs (1963) pointed out that using the normal distribution provides a good approximation if the standard deviation is less than 30 or if the range of observations does not exceed 114° (also see Agterberg 1974, Fig. 102). The following types of mean can be estimated:

AM (arithmetic mean): $\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i$

VM (vector mean): $\hat{\gamma} = \arctan \frac{\sum_{i=1}^n \sin x_i}{\sum_{i=1}^n \cos x_i}$

SVM (semicircular vector mean): $\hat{\gamma}_2 = \frac{1}{2} \arctan \frac{\sum_{i=1}^n \sin 2x_i}{\sum_{i=1}^n \cos 2x_i}$

VM and SVM apply to directed and undirected features, respectively.

There is a close connection between 2D circular and 3D spherical statistics. The features taken, for example, in this chapter are observed in 2D outcrops in the field. In the first example, they are approximately in 2D, because the rock layers containing them are subhorizontal. In the second example, they are 3D but can be regarded as 2D because they resulted from geological processes that took place at significantly different times, during the Hercynian and Alpine orogenies, respectively. In a so-called marked point process, the marks are values at the points (c.f. Stoyan and Stoyan 1996 or Cressie 1991). Thus, on maps showing azimuths and dips of

features at observation points for the second example the dips could be regarded as marks of the azimuths, or vice versa.

The body of publications dealing with statistics of orientation data is large. Introductory papers on unit vectors in the plane include Rao and Sengupta (1970). Statistical theory for the treatment of unit vectors in 2D (Fisher 1993) and 3D (Fisher et al. 1987) is well developed. The comprehensive textbook by Mardia (1972) covers both 2D and 3D applications. Pewsey and Garcia-Portugués (2020) is a more recent review pointing out that <https://git.ub.com/egarpor/DirectionalStatsbib> contains over 1700 references to publications on statistics of 2D and 3D directional features.

Doubling the Angles

It is useful to plot angular data sets under study in a diagram before statistical analysis is undertaken. Azimuth readings can be plotted on various types of rose diagrams (Potter and Pettijohn 1963). If the lines are directed, the azimuths can be plotted from the center of a circle and data within the same class intervals may be aggregated. If the lines are undirected, a rose diagram with axial symmetry can be used such as the one shown in Fig. 1. Then the method of Krumbein (1939) can be used in which the average is taken after doubling the angles and dividing the resulting mean angle by two. In Agterberg (1974), problems of this type and their solutions are discussed in more detail. Krumbein's solution is identical to fitting a major axis to the points of intersection of the original measurements with a circle. Axial symmetry is preserved when the major axis is obtained.

The three types of mean unit vector listed previously correspond to the following three types of frequency distribution:

Circular Error Probability,

Fig. 1 Axial symmetric rose diagram of the direction of pebbles in glacial drift in Sweden according to Köster (1964). (Source: Agterberg 1974, Fig. 99)

AM: normal (Gaussian) with frequency distribution $f_n(\theta) =$

$$\frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{\theta^2}{2\sigma^2}\right)$$

VM: circular normal (von Mises) with $f(\theta) =$

$$\frac{1}{2\pi I_0(\kappa)} \exp(\kappa \cdot \cos \theta)$$

SVM: semicircular normal with $f_2(\theta) =$

$$\frac{1}{\pi I_0(\kappa_2)} \exp(\kappa_2 \cdot \cos \theta)$$

In these expressions, θ (previously denoted as x) represents the angle measured clockwise from the pole (usually the north direction); $I_0(\dots)$ is the Bessel function of the first kind of pure imaginary argument.

Bjorne Formation Paleodelta Example

The Bjorne Formation is a predominantly sandy unit of Early Triassic age. It was developed at the margin of the Sverdrup Islands of the Canadian Arctic Archipelago. On northwestern Melville Island, the Bjorne Formation consists of three separate members which can be distinguished, mainly on the basis of clay content which is the lowest in the upper member, *C*. The total thickness of the Bjorne Formation does not exceed 165 m on Melville Island. The formation forms a prograding fan-shaped delta. The paleocurrent directions are indicated by such features as the dip azimuths of planar foresets and axes of spoon-shaped troughs (Agterberg et al. 1967). The average current direction for 43 localities of Member *C* is shown in Fig. 2a. These localities occur in a narrow belt where the sandstone member is exposed at the surface. The azimuth of the paleocurrents changes along the belt. The attitude of sandstone layers is subhorizontal in the entire study area.

The variation pattern (Fig. 3a) shows many local irregularities but is characterized by a linear trend. In the (U, V) plane for the coordinates (see Fig. 3b), a linear trend surface can be written as $x = F(u, v) = 292.133 + 27.859u + 19.932v$ (degrees). At each point on the map, x represents the tangent of a curve for the paleocurrent trend that passes through that point, or $\frac{dv}{du} = -\tan x$. It is readily shown that: $du = \frac{dx}{a_1 - a_2 \tan x}$ where $a_1 = 27.859$ and $a_2 = 19.932$. Integration of both sides gives:

$$u = C + \frac{1}{a_1^2 + a_2^2} [a_1 x - a_2 \log_e(a_1 \cos x + y \sin x)]$$

with $y = a_2$ if $\tan x > \frac{a_1}{a_2}$ and $y = -a_2$ if $\tan x < \frac{a_1}{a_2}$. The result is applicable when x is expressed in degrees. When $x \geq 360^\circ$, the quantity 360° may be subtracted from x , because azimuths are periodic with period 360° . The constant C is arbitrary. A value can be assigned to it by inserting specific values for u and v into the equation. For example, if

$u = 0$ and $x = 0$, $C = -0.7018$. It can be used to calculate a set of values for u forming a sequence of values for x ; the corresponding values for v then follow from the original equation for the linear trend surface. The resulting curves (1) and (2) are shown in Fig. 3b. If the value of C is changed, the curves (1) and (2) become displaced in the $x = 54.4^\circ$ direction. Thus, a set of curves is created that represents the paleocurrent direction for all points in the study area.

Suppose that the paleocurrents were flowing in directions perpendicular to the average topographic contours at the time of sedimentation of the sand. If curve (1) of Fig. 3b is moved in the 144.4° direction over a distance that corresponds to 90° in x , the result represents a set of directions which are perpendicular to the paleocurrent trends. Four of these curves which may represent the shape of the delta are shown in Fig. 4c. These contours, which are labeled *a*, *b*, *c*, and *d* satisfy the preceding equation for u with different values of C and with x replaced by $(x + 90^\circ)$ or $(x - 90^\circ)$. Definite values cannot be assigned to these contours because x represents a direction and not a vector with both direction and magnitude.

In trend surface analysis, the linear trend surface (also see Fig. 4a) has explained sum of squares $ESS = 78\%$. The complete quadratic and cubic surfaces have ESS of 80% and 84%, respectively. Analysis of variance for the step from linear to quadratic surface resulted in $\widehat{F}(3, 37) = \frac{(80-78)/3}{(100-80)/37} = 1.04$. This would correspond to $F_{0.60}(3, 37)$ showing that the improvement in fit is not statistically significant. It is tacitly assumed that the residuals are not autocorrelated as suggested by their scatter around the straight line of Fig. 3. Consequently, the linear trend surface as shown in Fig. 4a is acceptable in this situation. The 95% confidence interval for this linear surface is shown in Fig. 4b. Suppose that X is the matrix representing the input data. This is a so-called half-confidence interval with values equal to $[(p+1) \cdot F \cdot s^2(\bar{Y})]$ with $F = F_{0.95}(3, 40) = 2.84$ and $s^2(\bar{Y}) = s^2 \dot{X}_k (\dot{X}X)^{-1} X_k$ with residual variance $s^2 = 380$ square degrees.

All flow lines in Fig. 4a converge to a single line-shaped source. They have a single asymptote in common which suggests the location of a river. An independent method for locating the source of the sand consists of mapping the grade of the largest clasts contained in the sandstone at a given place. Four grades of large clasts could be mapped in the area of study. They are: (1) pebbles, granule, coarse sand; (2) cobbles, pebbles; (3) boulders, cobbles; and (4) boulders (max. 60 cm). The size of the clasts is larger where the velocity of the currents was higher. Approximate grade contours for classes 1–4 are shown in Fig. 4c for comparison. This pattern corresponds to the contours constructed for the paleodelta.

Circular Error Probability, Fig. 2 Variation of preferred paleocurrent direction along straight line coinciding with surface outcrop of Member C, Bjorne Formation (Triassic, Melville Island, Northwest

Territories, Canada); systematic change in azimuth is represented by trend line. (Source: Agterberg 1974, Fig. 12)

Directed and Undirected Unit Vectors

Directional features play an important role in structural geology. Basic principles were originally reviewed and developed by Sander (1948) who associated a three-dimensional (A, B, C) Cartesian coordinate system with folds and other structures. A-axis and C-axis were defined to be parallel to the directions of compression and expansion, respectively, with the B-axis

perpendicular to the AC-plane representing the main plane of motion of the rock particles. Two examples of Hercynian minor folds with clearly developed B-axes are shown in Fig. 5 (from Agterberg 1961) for quartzphyllites belonging to the crystalline basement of the Dolomites in northern Italy. Measurements on B-axes from these quartzphyllites were analyzed previously (Agterberg 1961, 1974, 2012) and are again used here.

Circular Error Probability, Fig. 3 Reconstruction of approximate preferred paleocurrent direction and shape of paleodelta from preferred current directions, Member C, Bjorne Formation, Melville Island. (After Agterberg et al. 1967). (a) Preferred directions of paleocurrent indicators

at measurement stations; 0-isopach applies to lower part of Member C only. (b) Graphical representation of solution of differential equation for paleocurrent trends. Inferred approximate direction of paleoriver near its mouth is N54.4 °E. (Source: Agterberg 1974, Fig. 13)

Stereographic projection using either the Wulff net or the equal-area Schmidt net (see, e.g., Agterberg 1974) continue to be useful tools for representing sets of directional features from different outcrops within the same neighbourhood or for directions derived from crystals in thin sections of rocks. Contouring on the net is often applied to find maxima representing preferred orientations, which also can be estimated using methods developed by mathematical statisticians, especially for relatively small sample sizes (see, e.g., Fisher et al. 1987).

Reiche (1938) used the vector mean to find the preferred orientation of directional features. Using a paleomagnetic data set, Fisher (1953) further developed this method for estimating the mean orientation from a sample of directed unit vectors. The frequency distribution of unit vectors may satisfy the so-called Fisher distribution $f(\theta, \phi) = \frac{\kappa}{4\pi \cdot \sinh \kappa} \exp(\kappa \cdot \cos \theta)$, which is the spherical equivalent of a two-dimensional normal distribution.

TRANSALP Profile Example

Figure 6 (based on map by Agterberg 1961) shows mean B-axes and schistosity planes in quartzphyllites belonging to the crystalline basement of the Dolomites in an area around the Gaderbach, which was part of the seismic Vibroseis and explosive transects of the TRANSALP Transect. The TRANSALP profile was oriented approximately along a north-south line across the Eastern Alps from Munich to Belluno with locally its position determined by irregular shapes of the topography (see, e.g., Gebrande et al. 2006).

Structurally, the quartzphyllites are of two types: in some outcrops the Hercynian schistosity planes are not strongly

folded and their average orientation can be measured. However, elsewhere, like in the examples of Fig. 6 and in most of the Pustertal to the east of Bruneck, there are relatively many minor folds (as illustrated in Fig. 5) of which the orientation can be measured. However, then it may not be possible to measure representative strike and dip of schistosity at outcrop scale. In the parts of the area where the strike and dip of schistosity planes can be determined, there usually are B-lineations for microfolds on the schistosity planes that also can be measured. Consequently, the number of possible measurements on B-axes usually exceeds the number of representative measurements on schistosity planes.

Figure 6 shows that the average strike of schistosity is fairly constant in this area but the average azimuth and dip of the B-axes is more variable. There is a trend from intermediate eastward dip of B-axes in the southern parts of the region to subvertical attitude in the north. This systematic change can also be seen on Schmidt net plots for the six measurement samples along the Gaderbach (Agterberg 1961, Appendix III). In Fig. 7, the B-axes measured along the Gaderbach are projected onto a North-South line approximately parallel to the average orientation of the TRANSALP profile.

In a general way, the results of the preceding linear unit vector field analysis confirm the earlier conclusions on North-South regional change in average B-lineation attitude. Original estimates of mean B-axis orientations of which some are shown in Fig. 6 were obtained by separately averaging the azimuths and dips. Table 1 shows results from another test. In Fig. 7 such average values for the six measurement samples (Method 1) are compared with ordinary unit vector means (Method 2) at mean distances south of the (Periadriatic) Pusteria Lineament near Bruneck. Differences between the two sets of mean azimuth and dip values are at most a few degrees indicating that regionally, on the average, there is a

Circular Error Probability, Fig. 4 (a) Linear trend for data of Fig. 3a. Computed azimuths are shown by line segments for points on regular grid, both inside and outside exposed parts of Member C; flow lines are based on curves 1 and 2 of (c). (b) Contour map of 95% half-confidence interval for A; confidence is greater for area supported by observation points. (c) Estimated topographic contours for delta obtained by shifting

curve 1 of Fig. 3b, 90° in the southeastern direction (= perpendicular to isoazimuth lines), and then moving it into four arbitrary positions by changing the constant C. Contoured grades of largest clasts provide independent information on shape of delta. (Source: Agterberg 1974, Fig. 41)

Circular Error Probability, Fig. 5 Two examples of minor folds in the Pustertal quartzphyllite belt. Left side: East-dipping minor folds near Welsberg (Monguelfo). Right side: ditto along TRANSALP profile near

subvertical contact with Permotriassic (grid coordinates 206–767; part of MS112, see Fig. 8). (Source: Agterberg 2012, Fig. 1)

Circular Error Probability, Fig. 6 Schematic structure map of surroundings of TRANSALP profile (TAP) in tectonites of crystalline basement of the Dolomites near Bruneck. Arrows represent average azimuths of B-axes for measurement samples. Average dips of B-axes are also shown. Average *s*-plane attitudes are shown if they could be determined with sufficient precision. MS: Measurement Sample as in Agterberg (1961, Appendix II). PI: Permian Intrusion; PL: Periadriatic Lineament. Coordinates of grid are as on 1:25,000 Italian topographic maps. (Source: Agterberg 2012, Fig. 5)

Circular Error Probability, Fig. 7 Azimuths (diamonds) and dips (triangles) of B-axes from six measurement samples along Gaderbach shown in Fig. 6. Note that along most of this section, the B-axes dip

nearly 50° East. Closest to the Periadriatic Lineament, their dip becomes nearly 90° SSW (also see Table 1). (Source: Agterberg 2012, Fig. 6)

Circular Error Probability, Table 1 Comparison of average orientations obtained by two methods. *MS*: measurement sample; distance in km south of Insubric Line; *Method 1*: average azimuth/dip; *Method 2*: Fisher azimuth/dip; Azimuth and dip are given in degrees

MS #	Distance	Method 1	Method 2
92	2.38	217/77	220/78
95	4.38	104/58	103/58
112	7.08	101/51	100/52
96	8.68	86/39	85/41
111	10.58	113/52	113/53
112	11.88	104/43	102/44

dip rotation from about 45° dip to the east in the south to about 80° dip in the north accompanied by an azimuth rotation of about 120° from eastward to WNW-ward.

Widespread occurrence of steeply dipping B-axes near the Periadriatic Lineament and along the southern border of the Permian (Brixen granodiorite) intrusion, however, is confirmed by results derived from other measurement samples. The rapid change in average azimuth that accompanies the B-axis steepening is probably real but it should be kept in mind that the azimuth of vertical B-axes becomes

indeterminate. The northward steepening of attitudes of *s*-planes in the northern quartzphyllite belt to the West of Bruneck from gentle southward dip near Brixen is probably due to neo-Alpine shortening. The northward steepening of the B-axes near Bruneck, which on average are contained within the *s*-planes, could be due to Neo-Alpine sinistral movements along the Periadriatic Lineament and south of the Permian (Brixen granodiorite) intrusion.

Summary and Conclusions

Circular error probability is associated with two-dimensional directional features that are observed in different types of rock. Examples in sedimentary rocks include cross-bedding, ripple marks and features associated with turbidity currents. Crystals in igneous rocks may display preferred orientations. Microfolds and minor folds in structural geology provide other examples. Different procedures must be used for directed and undirected features, especially in sedimentology. Elongated pebbles in Sweden were used to illustrate one type of statistical method to treat undirected features. There is a

close association between spherical and circular error probability. Directional cross-bedding in sandstones of the Early Triassic Bjorne Formation in the Canadian Arctic was used to reconstruct the shape of a paleodelta with approximate location of the river associated with it. In structural geology the preferred orientations of minor folds in the Hercynian basement of the Dolomites in Northern Italy were taken as an example. Although these features are three-dimensional, their azimuths and dips can be analyzed separately by using a marked 2D model. The Hercynian minor folds were subjected to rotations during the Alpine orogeny.

Definitions

- Cloud computing:** A technique that virtualizes the IT resources and delivers them to users over the Internet with pay-as-you-go pricing and on-demand basis.
- Cloud service:** The commodity services delivered by cloud computing vendors to end-point users, including the storage, server, application, and networking.

Background

The exploding volume of Earth observations is driving scientists to seek for better schemes of computing and storage. Large-scale and high-performance computing is more necessary in operational use today than 10 years ago. Many institutes and commercial companies are working intensively to provide such computing capabilities and make them available

to scientists. Cloud has become one of the major computing resource providers in geosciences (Hashem et al. 2015). This entry reviews the existing cloud platforms, cloud-native services, and the schemes of using cloud resources in geoscientific research. This entry offers insights on how to correctly leverage clouds in geoscientific research and how the clouds and geosciences should thrive together in the future.

What Is Cloud Computing?

The leading cloud provider, Amazon Web Service, explains it in this way: “*Cloud computing is the on-demand delivery of IT resources over the Internet with pay-as-you-go pricing. Instead of buying, owning, and maintaining physical data centers and servers, you can access technology services, such as computing power, storage, and databases, on an as-needed basis from a cloud provider*” (<https://aws.amazon.com/what-is-cloud-computing/>). The definition shows two major reasons that are backing the requirements for cloud computing: server costs and on-demand needs. For example, if a geoscientist wants to serve a valuable dataset to the public, in old days the scientist will have to buy a server and plant it in a data center and pay the data center for the costs on electricity, network, air conditioning, room space, racks, and on-site staff (Dillon et al. 2010). Meanwhile, all the risks are on the scientist, such as disk failures, network interruption, vulnerability fix, Internet attack, etc. In a while, the scientist will find the research team in an awkward situation working significantly on disk replacing, network testing, and vulnerability fixing. As the owner of the server, they need to pay a lot to survive the server online or off-line. Even worse, many servers in universities’ data centers are never running on 100% of capability. Most of the computing hours are wasted with servers running idle, which is a big waste of the research resources and results in a serious unbalance between research hours and server maintenance hours.

To reverse the unbalance, cloud computing was proposed, implemented, and instantly gained popularity in server administrators. Compared to the old routine of server-hosting businesses, *cloud computing provides a new paradigm by adding a virtualization layer on top of the physical hardware layer*. The *virtualization layer* is powered by the virtual machine technique which can create multiple new virtual machines from one physical machine. The virtual machines use the host’s CPU, memory, and disks, but running separately. From the user perspective, the virtual machines have no differences from a real physical machine. Users can do everything they did on a physical machine on the virtual machines. In cloud computing, each virtual machine is called an instance. In cloud computing, users only interact with instances and do not have access to the physical hardware level. Cloud data centers host tens of thousands of servers,

link them into cloud clusters, sell the computing hours to the public by creating separated virtualized instances, and provide web-based interfaces or remote-messaging channels (such as SSH and RESTful API) for the users to manipulate the instances remotely (users normally cannot access the data centers physically). The bills will be calculated based on the occupied computing hours and the instance type. The rates (cost per hour) vary across the types (configuration of CPU, GPU, memory, storage, and network) and the location of the data centers. For example, the rate for AWS EC2 m5.xlarge at US East (N.Va) data center is \$0.192 per hour, the rate for the same instance at Asia Pacific (Sydney) data center is \$0.24 per hour (<https://aws.amazon.com/emr/pricing/>). Overall, cloud computing is a scheme in which the computing resources are pooled together and disseminated in the form of virtual machines over the Internet to reduce the labor and financial burdens on both the owners and users of the IT resources.

Thinking of the computing resources as commodities, the cloud providers are sellers and the users are consumers. **Cloud services** denote all the service commodities provided by cloud platforms. To better commercialize the clouds, cloud providers have made many innovative developments to customize their services to fit in users’ scenarios and further reduce the workloads on the user side. This customization categorizes cloud computing into several types (Armbrust et al. 2010):

- **Infrastructure as a Service (IaaS)** (Bhardwaj et al. 2010) offers complete instance machines including all computing resources including data storage, servers, applications, and networking. Users are responsible for managing all four kinds of resources. Examples: AWS EC2, Google Compute Engine, Digital Ocean, Microsoft Azure, and Rackspace.
- **Platform as a Service (PaaS)** (Pahl 2015) offers a programming language execution environment associated with a database. It encapsulates the environment where users can build, compile, and run their programs without worrying about the underlying infrastructure. In this service model, users only manage software and data, and the other resources are managed by the vendors. Examples: AWS Elastic Beanstalk, Engine Yard, and Heroku.
- **Software as a Service (SaaS)** (Cusumano 2010) offers pay per use of application software to users. Users do not need to install software on PC and access the software via a web browser or lightweight client applications. Examples: Google ecosystem Apps (Gmail, Google Docs), Microsoft Office365, Salesforce, Dropbox, Cisco WebEx, Citrix GoToMeeting, and Workday.

There are many more types, such as Artificial Intelligence as a Service, Hadoop as a Service, Storage as a Service, Network as a Service, Backend as a Service, Blockchain as a Service, Database as a Service, Knowledge as a Service,

etc. (Tan et al. 2016). Users should consult cloud experts to analyze which cloud computing model is the most suitable for their use cases. An appropriate selection would save significantly in costs while gaining more from the investments.

Using Cloud in Geosciences

Geoscientists on Cloud

The paradigm of cloud computing makes it possible for scientists to only buy necessary computing hours and storage space instead of owning entire real servers, and thereafter get rid of all the hassles in server maintenance. With cloud computing, the scientist could worry less about the tedious technical issues, and pay for the resources that are used on demand and avoid the constant waste of idle servers. It is an evolution in scientific research efficiency and boosts the utilization ratio of the computing resources. Besides, it is easier to scale up the scientific models to a larger extent on big data, which was impossible before for many scientists in the old routine of computing schemes. Similar to the other sharing economy schemes, cloud computing takes advantage of its vast number of users to average the huge hardware maintenance costs and lower the bills on each user.

Geoscientific Use Cases

Geosciences have numerous study cases that meet the scenario requirements of cloud computing, e.g., earthquakes, landslides, land cover land use, volcano, rainfall, groundwater, snow, ice, climate change, hurricane, agriculture, wildfire, air quality, etc. Each research domain has undergone many years of observation activities and accumulated a lot of datasets. For example, IRIS (incorporated research institutions for seismology) Data Management Center (DMC) has operated a public repository of seismological data of three decades. IRIS offers a wide and growing variety of services that Earth scientists in over 150 countries worldwide reply on through web services. IRIS DMC archive is nearing one petabyte in volume. The funding of IRIS is mainly coming from the National Science Foundation, and the annual cost is around \$30 million (<https://ds.iris.edu/ds/newsletter/vol20/no2/498/geoscicloud-exploring-the-potential-for-hosting-a-geoscience-data-center-in-the-cloud/>). A significant amount is spent on maintaining the data repository to serve all the downloading requests from all over the world. Cloud computing is considered as a promising solution to significantly lower the data-hosting costs and put more funding on data-collection and data-mining activities.

Cloud-Based Data Storage

Most use cases of cloud in geosciences focus on storage, such as storing spatial data that can be accessed remotely. For big spatial data, cloud storage provides a more elastic, efficient,

robust storage service than conventional storage plans. The disks on the servers are consumable products that will certainly fail after reading and writing data onto the disks for a certain number of times (e.g., tens of million times). The standard warranty of a normal hard disk is about 5 years. RAID (Redundant Array of Independent Disks) is a common practice to ensure data security when some disks reach the end of life. RAID creates a pool of disks and stores the data scattered among all the disks instead of relying solely on one disk. Once a disk is detected with alert status, the data on it will be automatically transferred to other healthy disks. Some RAID (e.g., RAID-5) will store all the data duplicated, so when some disk regions are damaged, it can recover the data from the other copy. However, RAID will run through all the disks in every I/O operation which significantly decreases the average life of the disks. RAID needs to replace the disks in alert status as quickly as possible, otherwise, all the data will be lost if the percentage of failed disks reaches a certain ratio. Scientists might be exhausted to do the routine RAID check. Cloud data centers have on-site engineers who can do the disk check and replacement. Data is safer in the cloud than in individual small data centers that are less attended.

Cloud-Based Data Analysis

With the continuous efforts by the generations of scientists working on deploying sensors and building data repositories, geoscientists have many direct channels to get the required data to support their research. The fact today is that *geoscientists do not lack data in most times*. The real missing piece is the capability to allow scientists to manipulate the data in a time-wise and cost-wise manner. Artificial intelligence and machine learning algorithms are being used in geospatial analysis and run against spatial data to automate the processing and reveal insights (Sun et al. 2020). Spatial analysis, such as network analysis, clustering, pattern extraction, classification, and predictive modeling, poses more intelligence for information extraction. However, intelligent algorithms come with higher complexity which requires a more efficient solution to process the big amount of data. For example, it takes about 10 min for a PC to do a buffer process on the road network of Washington D.C. but takes weeks to buffer the road network of the entire world. The time cost increases at an exponential rate over the volume of the input datasets. Big data processing is one of the major applications of clouds. Cloud can create multiple instances that work simultaneously on the same task. Each instance processes one portion of the dataset (Map), and a reduce process will summarize the results from the instances into one result (Reduce). This parallel processing scheme is called MapReduce. Typical Map Reduce software includes the most widely used Apache Hadoop, Apache Spark, and Google Earth Engine (GEE) (Gorelick et al. 2017). For example, GEE is a cloud-based platform for planetary-scale geospatial analysis that brings

Google massive computational capabilities to process tremendous amounts of remote-sensing data products to help scientists to study deforestation, drought, disaster, disease, food security, ocean, water management, climate, and environment protection. These cloud-based big data-processing platforms have been heavily utilized and driven a series of significant discoveries in geoscience communities recently.

Challenges and Opportunities

Turning Geoscientific Applications to Cloud Native

Cloud native is an approach to building and running applications that are small, independent, and loosely coupled. Cloud-native applications are purposefully built for the cloud model to take advantage of the full benefits of clouds to enable resilience and flexibility of the application. Cloud-native app development typically includes DevOps, Agile methodology, microservices, cloud platforms, containers such as Kubernetes and Docker, and continuous delivery. However, the existing applications of geosciences are not cloud native. Most of them need wrapping and reprogramming, which may cause a series of compatibility issues between the traditional application environment and the container environment. Geoscientific applications are large programs that are not suitable to be packaged as microservices and need a breakdown. Geoscientific workflows should be itemized into several small-granule processes and run on the clouds with scalability and elasticity (Sun et al. 2019).

Managing Cloud Expenses

In most cases, cloud computing could save money. Instead of a onetime payment, the cloud cost is recurring based on usage. For applications with big data and a lot of users, more cloud resources will be used to cope with the huge data volume and the increasing requests. Correspondingly, the cost will rise as well and might make the entire bill unaffordable. For short-lived or small-scale projects, it is expensive to transfer all the data into public clouds. Using clouds needs to spend optimization which aims to generate the largest possible saving with predictive analytics and actionable resource purchasing recommendations. It is financially wise to automatically identify idle resources, unused instances, and shut them down to save costs. The cloud platforms usually provide cost optimization options by financial analytics and governance policies for automatically releasing the unused resources and decreasing the costs.

Data Security and Privacy

This is the top concern of most users on the cloud. Uploading data into the cloud feels like turning in the control over the data to a third party. This is true from a certain perspective, as

the data is physically transferred from users' machines to some machines owned by another institute. But from an engineering perspective, the cloud-based storage is more secure than local disks. Besides the common credential protection (password), the state-of-the-art cloud storage uses professional security methods such as firewalls, traffic monitoring, event logging, encryption, and physical security to keep the data private even though they are on a publicly accessible server. Another benefit of using the cloud is easy updating to fix vulnerabilities. Users do not need to worry about occasionally upgrading their PC systems to fix the newly discovered vulnerabilities. It is also smoother to apply the new security technology provided by cloud vendors on the fly. On the other side, users must follow the vendors' security guidelines, and negligent use could compromise even the best protection.

Governance

In industries, cloud computing governance creates business-driven policies and principles that establish the appropriate degree of investments and control around the life-cycle process for cloud services (http://www.opengroup.org/cloud/gov_snapshot/p3.htm). It ensures that all the sponsored activities are aligned with the project objective. For geosciences, one fundamental measure in governance is whether the activity directly contributes to problem-solving. The priority should be categorized based on the job significance in the entire workflow. In addition, the governance of the cloud is also an implementation of project management policies. The management models and standards for team members and the end-point users are going to be enforced in the form of a cloud computing governance framework. Coordinating the team members to work simultaneously on the cloud is another challenge facing the geoscientists and also an important research area for cloud vendors to innovate and advance their cloud services.

Private Cloud

In reality, many scientists will not use the public clouds out of various reasons (cost and trust); however, they would like to use the cloud features within their institutes. A private cloud would be the answer. Building a cloud is similar to building a cluster or supercomputer, all of which need multiple servers (more than one), including one management server and several client/slave servers. All the servers are connected via high-speed networks to pass messages among them. Operating systems of the member servers are mostly Linux-based, even in Microsoft Azure, because of its better support for virtualization hypervisor (software used for creating virtual machines). The cloud platform software includes OpenStack, CloudStack, Eucalyptus, and OpenNebula. Among them, OpenStack is the choice of most industrial companies, e.g.,

RedHat, IBM, Rackspace, Ubuntu, SUSE, etc. The installation of OpenStack is complicated. For scientific teams, it is better to consult cloud professionals before installing the servers.

Summary

This entry introduces the concept of cloud computing and the situation of using clouds in geosciences. Cloud computing has been proven as an effective solution to lift the bar for scientists to access and process the big geoscientific datasets. More and more use cases of cloud computing in geosciences are expected soon. There are several associated challenges with the transition from conventional computing paradigm to cloud, including transforming the old geoscientific models into cloud-native applications, managing cloud expenses over time, ensuring data security and privacy within the cloud data centers, coordinating the team efforts to work simultaneously on the cloud, and creating private clouds for scientists to integrate computing resources and serve the users within the institutions. Cloud vendors could take on these challenges to advance their cloud services to further extend their collaboration with geoscientists and assist them to solve critical scientific problems that are insolvable before.

Cluster Analysis and Classification

Antonella Buccianti and Caterina Gozzi
Department of Earth Sciences, University of Florence,
Florence, Italy

Definition

Cluster analysis and classification – a family of data analysis methods that attempt to find natural groups clearly separated from each other, thus giving indications about potential classification rules to be exploited in discriminant analysis procedures.

Historical Material

Our numerical world produces masses of data every day in earth sciences as well as in several other fields of investigation. The analysis of this big available data offers the possibility to exploit unknown paths leading to important advances in knowledge. However, the management of high-dimensional data, with the aim to extract as much information as possible, needs adequate methods and procedures. Cluster analysis and classification is one of the most interesting fields of statistical analysis both as explorative tool of the data grouping structures and model-based techniques for classification.

The aim of cluster analysis is to find meaningful groups in data internally coherent and well separated from others. The members of the groups joint some common features in the multivariate space, and this peculiarity is enhanced by using appropriate similarity/dissimilarity measures. The grouping of cases in cohesive groups dates back to Aristotle in his *History of Animals* in 342 B.C., while in natural and taxonomical sciences, a typical example is referred to Linnaeus (1735) for plant and animals. The systematic use of numerical methods in searching for groups in quantitative data refers to anthropological studies (Czekanowski 1909) where the measures of similarity between objects began to be the focus. In the 1950s, several advancements were proposed by considering the way of linking cases in a hierarchical procedure of aggregation whose final graphical result was the dendrogram (a tree diagram that shows the hierarchical relationships between objects). In the 1960s, a turning point is represented by the publication of the book of Sokal and Sneath (1963), and some recent interesting developments concern the model-based clustering where each group is modeled by its own probability distribution, thus obtaining a finite mixture model (Bouveyron et al. 2019). The application of cluster analysis for compositional data has also been discussed

considering the constrained working sample space (Aitchison 1986) and the implications to manage distances inside it (Templ et al. 2008). Compositional data, in fact, describe parts of the same whole and are commonly presented as vectors of proportions, percentages, or concentrations. Since they are expressed as real numbers, people are tempted to interpret or analyze them as real multivariate data, leading to paradoxes and misinterpretations.

When applied to geological and environmental data, cluster analysis can be used to group the variables, with the aim to highlight the correlation structure of the data matrix or to cluster cases into homogeneous subsets for subsequent analysis (e.g., discriminant analysis or mapping): these two different ways are known in literature as R-mode and Q-mode, respectively.

Essential Concepts and Applications

In cluster analysis, there are basically two different paths noting if the case is allocated to just one cluster (hard clustering) or if it is distributed among several clusters by considering a certain degree of association (fuzzy clustering, Dumitrescu et al. 2000).

The input of most of the hierarchical clustering algorithms is a distance matrix (distances between observations) $n \times n$ generated from an input original matrix $n \times p$ (n = number of cases, p = number of variables). Many different distance measures can be considered as a measure of similarity between cases in the multivariate space. An interesting deepening can be found in Shirkhorshidi et al. (2015).

The Minkowski family includes the Euclidean and Manhattan distances, which are particular cases of the Minkowski distance. The latter is defined by:

$$d_{\min} = \left(\sum_{i=1}^n |x_i - y_i|^m \right)^{1/m} \quad (1)$$

with $m \geq 1$ and x_i and y_i two vectors in n -dimensional space. The distance performs well when the data clusters are isolated or compacted, otherwise the large-scale attributes dominate the others. The Manhattan distance is a special case of the Minkowski one at $m = 1$ and like the previous one is sensitive to outliers. The Euclidean distance is a special case of the Minkowski one when $m = 2$ and similarly to this one performs well in the same conditions. It is very popular in cluster analysis, but it has some drawbacks. In fact, even if two data vectors have no attribute values in common, it might occur that they have a smaller distance than the other pair of data vectors containing the same attribute values. Another problem with Euclidean distance, as a family of the Minkowski metric, is that the largest-scaled feature could

dominate the others. Data normalization is a common solution to overcome this problem.

Average distance is a modified version of the Euclidean distance developed to try to solve the previous problems. For two data points x and y in a n -dimensional space, the average distance is defined as:

$$d_{\text{ave}} = \left(\frac{1}{n} \sum_{i=1}^n (x_i - y_i)^2 \right)^{1/2} \quad (2)$$

The weighted Euclidean distance is instead defined as:

$$d_{\text{we}} = \left(\sum_{i=1}^n w_i (x_i - y_i)^2 \right)^{1/2} \quad (3)$$

where w_i is the weight given to the i th component to be used if the information of the relative importance according to each attribute is available.

Chord distance was proposed to overcome the problems of the scale of measurements and the critical issues of the Euclidean one. It is defined as:

$$d_{\text{chord}} = \left(2 - 2 \frac{\sum_{i=1}^n x_i y_i}{\|x\|_2 \|y\|_2} \right)^{1/2}, \quad (4)$$

where $\|x\|_2$ is the L^2 norm $\|x\|_2 = \sqrt{\sum_{i=1}^n x_i^2}$.

Mahalanobis distance, in contrast with the previous ones, is a data-driven measure, and it is used to extract hyper-ellipsoidal clusters tone down distortion caused by linear correlation among features. It is defined by:

$$d_{\text{mah}} = \sqrt{(x - y) S^{-1} (x - y)^T} \quad (5)$$

where S is the covariance matrix of the data set.

The cosine similarity measure is given by:

$$\cos_{xy} = \frac{\sum_{i=1}^n x_i y_i}{\|x\|_2 \|y\|_2} \quad (6)$$

where $\|y\|_2$ is the Euclidean norm of vector $y = (y_1, y_2, \dots, y_n)$ defined as $\|y\|_2 = \sqrt{y_1^2 + y_2^2 + \dots + y_n^2}$. This measure is invariant to rotation but not to linear transformations. It is also independent of the vector length.

When the target of the analysis is the clustering of variables, a similarity matrix $p \times p$ will be generated by the $n \times p$ original one, by choosing a correlation measure.

The Pearson correlation coefficient is widely used, even if it is very sensible to outliers; it is defined by:

$$r_{xy} = \frac{\sum_{i=1}^n (x_i - \mu_x)(y_i - \mu_y)}{\sqrt{\sum_{i=1}^n (x_i - \mu_x)^2} \sqrt{\sum_{i=1}^n (y_i - \mu_y)^2}} \quad (7)$$

where μ_x and μ_y are the means for x and y , respectively.

Agglomerative techniques start considering that each sample forms its own cluster then enlarging the clusters stepwise with new contributions, thus linking the most similar groups at each step. The process ends when there is one single cluster containing all the cases. On the other hand, divisive clustering starts with one cluster containing all samples and then successively splits this into groups in subsequent steps. This reverse procedure generally requires intensive calculus.

To link clusters in the agglomerative procedure, several different methods exist. The best known are average linkage, complete linkage, and single linkage (Kaufman and Rousseeuw 2005). The average linkage method considers the averages of all pairs of distances between the cases of two clusters. The two clusters with the minimum average distance are combined into one new cluster. Complete linkage

(or farthest-neighbor method) looks for the maximum distance between the samples of two clusters. The clusters with the smallest maximum distance are combined. Single linkage (or nearest-neighbor method) considers the minimum distance between all samples of two clusters. The clusters with the smallest minimum distance are thus linked.

The dendrograms obtained with the previous linking methods will show some differences. The single linkage will give cluster chains, complete linkage very homogeneous clusters in the early stages of agglomeration, and small resulting clusters, average linkage a compromise solution between the two mentioned methods. The Ward method (Kaufman and Rousseeuw 2005) is an alternative to the single link procedure able to create compact clusters, even if computationally intensive. Instead of measuring the distance directly, it monitors the variance of clusters during the merging process, keeping the growth as small as possible, by using the within-group sum of squares as a measure of homogeneity.

In the dendrogram, the horizontal line indicates the link between cases in clusters, whereas the vertical axis is related to the similarity, that is, to the chosen measure of distance/correlation. The axes can be inverted without problems. The linking of two groups at a large height indicates strong dissimilarity and vice versa. If the dendrogram is cut at a given

Cluster Analysis and Classification,

Fig. 1 Dendrogram for the chemical composition of water data sampled in a sedimentary aquifer (Minkowski distance and complete linking method)

height, the assignation of the cases to a distinct cluster can be obtained and, eventually, their spatial distribution can be visualized.

To demonstrate the procedure, a set of samples defining the chemical composition of an aquifer mainly developed in a sedimentary context has been chosen. The $n \times p$ basic matrix was given by $n = 30$ cases and $p = 7$ variables, representing the main chemical components: Na^+ , K^+ , Ca^{2+} , Mg^{2+} , HCO_3^- , Cl^- , and SO_4^{2-} , all expressed in mg/L. The dendrograms based on the cited anions and cations are reported in Figs. 1, 2, and 3 for the similarity matrix $n \times n$ considering the same similarity metric (Minkowski) but different linkage methods (complete, single, and average). The numbers on the vertical and horizontal axes are related to the label of the cases and to the measure of closeness of either individual data points or clusters.

The figures highlight the differences in using different linkage methods due to the hierarchical way used to construct the clusters and to associate cases to them, step by step, as previously reported. However, some groups of data appear to be well characterized and homogeneous, while others (e.g., 22 and 23, 9, 10, 29 and 30) need more inspection to verify the origin of their isolated behavior, as reported in Table 1. At this stage of the investigation, the possibility to map data will help

to associate the presence of the clusters with possible environmental drivers such as lithology, depth of the well, climate, giving interesting information about processes, and forcing variables.

In the context of geoscience, cluster analysis may be very useful to unravel the complexity of nature and its laws, opening paths for classification rules of unknown cases, thus representing the explorative basic tool of discriminant analysis.

When the aim of the investigation is the analysis of the relationships among variables, the Pearson correlation matrix $p \times p$ can represent the basis for cluster analysis. Results are reported in Fig. 4 by using the average linkage method. No appreciable differences were obtained changing the similarity measure (e.g., the sample Spearman rank correlation between variables) or the linking method. The cluster analysis enhances the relationships characterizing water chemistry revealing a strong link among Na^{2+} and HCO_3^- and a more isolated behavior of K^+ , perhaps related to its complex biogeochemical cycle and possible anthropical contribution due to the extensive use of fertilizers in agriculture. The identification of groups of variables helps in evaluating which type of water-rock interaction processes can be considered in the investigated sedimentary context; for example, the

relationship among SO_4^{2-} and Ca^{2+} invites to check for the presence of sulfatic rocks while that between HCO_3^- and Na^+ to explore the role of cation exchange in the presence of clays.

In contrast to hierarchical clustering methods, partitioning methods require to a priori know the number of clusters (Kaufman and Rousseeuw 2005). A popular partitioning algorithm is the k-means algorithm that works minimizing the average of the squared distances between cases and their cluster centroids. Starting from k initial cluster centroids, the algorithm assigns the observations to their closest centroids using a given distance measure. Then, the cluster centroids are recomputed and iteratively the reallocation of the data points to the closest centroids performed. In this framework, Manhattan distance is used for k-medians when the centroids are defined by the medians of each cluster rather than their means. Several clustering methods have been proposed by Kaufman and Rousseeuw (2005) and are contained in several software packages (SPSS, Matlab, R) as the PAM (Partitioning Around Medoids) method that minimizes the average distances to the cluster medians, like the k-medians, and the CLARA (Clustering Large Applications) based on random sampling to reduce computing time and RAM storage problems.

Two different concepts of validity criteria need to be considered to evaluate the performance of a clustering procedure. External criteria compare the obtained partition with a partition that is known a priori and several indices can be used to do it (Haldiki et al. 2002). On the other hand, internal criteria are cluster validity measures that evaluate the clustering results of an algorithm by using only quantities and features inherent in the data set based on within and between cluster sums of squares, analogous to the multivariate analysis of variance (MANOVA), as the average silhouette width of Kaufman and Rousseeuw (2005).

Data Problems in the Context of Cluster Analysis

In multi-element analysis of geological materials, elements occur in very different concentrations so that, when methods exploring the variance-covariance structure are used, the variable with the greatest variance will have the greatest effect in the outcome. Consequently, variables expressed in different units should not be mixed or, as an alternative, the use of adequate transformation and standardization techniques (i.e., centering and scaling the data by using also a robust

version of mean and standard deviation, such as median and MAD for skewed variables) is needed.

The presence of outliers can have severe effects on cluster analysis affecting the distance measures and distorting the underlying data structure. Thus, it is advisable to remove the outliers prior to the application of the clustering procedure or to adopt methods able to handle them (Kaufman and Rousseeuw 2005). From this point of view, the use of explorative univariate and bivariate tools (e.g., histograms, box plots, binary diagrams) is fundamental before proceeding with every multivariate methodology to probe the data structure.

The method of substitution of censored data can have a big effect on the results of the clustering procedure, particularly when a high percentage of cases are substituted with an identical value (e.g., the detection limit or its percentage). The elimination of variables characterized by a large amount

of data below the detection limit often represents the only solution. However, with the aim of not losing the information, these variables can be transformed into dichotomic variables (values below and above the detection limit transformed in 0 and 1, respectively) so that a contingency table can be realized cross-correlating the clusters obtained by the analysis without them and the variables with dichotomic behavior.

Compositional (closed) data can also be a problem in cluster analysis since they pertain to the simplex sample space and not the real one (Aitchison 1986), thus compromising the correct use of every similarity/distance measure. One of the transformations of the log-ratio family, in particular the log-centered or the isometric one, should be applied or the use of the Aitchison distance promoted (Templ et al. 2008).

Cluster Analysis and Classification, Fig. 4 Dendrogram for the chemical composition of water data sampled in a sedimentary aquifer. The linking method was given by the average linkage and the similarity measure by the Pearson correlation coefficient

Conclusions

Cluster analysis is widely used in geological sciences as an exploratory methodology to verify the presence of natural groups in data. From this point of view, cluster analysis is not a statistical inference technique, where parameters from a sample are assessed as possibly being representative of a population. Instead, it is an objective methodology for quantifying the structural characteristics of a set of observations. However, two critical issues must be considered, the representativeness of the sample and multicollinearity. In the first case, the researcher would be confident that the obtained sample is truly representative of the population and the presence of multimodality or outlier cases would be carefully monitored in single variables (univariate analysis) and in the multivariate distribution. In the second case, the attention must be posed to the extent to which a variable can be explained by the other variables in the analysis. In this context, the use of clustering techniques with compositional data is very critical due to the constrained interrelationships among all the variables.

As an alternative, model-based (Mclust) clustering can be used. It is not based on distances between the cases but on models describing the shape of possible clusters. The algorithm selects the cluster models (e.g., spherical or elliptical cluster shape) and determines the cluster memberships of all cases for solution over a range of different numbers of clusters. The estimation is done using the expectation maximization (EM) algorithm (Bouveyron et al. 2019).

Definitions

Definition 1 Compositional data (CoDa) are vectors with strictly positive components that carry relative information. Consequently, the quantities of interest are ratios between components.

CoDa represent parts of some whole, like, e.g., the geochemical composition of a rock sample, which states the proportion of each of the different elements present in the sample. The proportion can be expressed in percentages, as is usually done for major element oxides, or in ppm or ppb, as is ordinarily the case for trace elements. The change from percentages to ppm is attained by multiplying the observed values by a constant, and it is assumed that they still carry the same compositional information. The vectors are then proportional, as they are different representations of the same composition. They are equivalent compositions and constitute an equivalence class. A typical representation is as vectors of strictly positive components with constant sum, which is very convenient from the mathematical point of view. For a graphical representation, see Fig. 1. There are many examples in the geosciences, like the mineral composition of a rock, or the geochemical composition of a sample. The representation of such data in ternary diagrams has a long tradition in this field.

Definition 2 Composition. A composition is a vector of D components taking values in the positive orthant of real space, $\mathcal{R}_+^D$, that carry relative information. It is custom to call

them *parts*, a term suggested by Aitchison (1982) to avoid confusion with real variables. In order to represent a composition $\mathbf{x} = [x_1, x_2, \dots, x_D]$ in the simplex all parts are divided by their sum and multiplied by κ ,

$$\mathcal{C}\mathbf{x} = \left[\frac{\kappa x_1}{\sum_{i=1}^D x_i}, \frac{\kappa x_2}{\sum_{i=1}^D x_i}, \dots, \frac{\kappa x_D}{\sum_{i=1}^D x_i} \right], \quad \kappa > 0, \quad (1)$$

where the components (parts) of $\mathcal{C}\mathbf{x}$ add up to κ . $\mathcal{C}\mathbf{x}$ is called closure of $\mathbf{x}$ to the constant κ ; it is a composition equivalent to $\mathbf{x}$. Usually $\kappa = 1$ or $\kappa = 100$.

A random composition, $\mathbf{X} = [X_1, X_2, \dots, X_D]$, is a composition whose parts are random variables. In order to determine the sample space of the parts it is convenient to consider $\mathbf{Y} = \mathcal{C}\mathbf{X}$. The parts of $\mathbf{Y}$, Y_i , are positive and add to the closure constant $\kappa > 0$. Then, the values of Y_i are in the D -part simplex satisfying $\sum_{i=1}^D Y_i = \kappa$.

The notation in capitals, like $\mathbf{X}$, is used for random compositions and the lower case, as $\mathbf{x}$, for realizations of the random composition or for fixed values. The notation with capitals is also used for denoting generic parts; for instance, in a geochemical analysis, $X_1 \equiv \text{Ca}$, $X_2 \equiv \text{Na}$ refers to the parts Ca and Na, respectively, in a generic sense.

Although the D -part simplex is only a subset of $\mathcal{R}^D$ space, quite often, it is assumed that operations and metrics of $\mathcal{R}^D$, the ordinary Euclidean geometry, is valid for the analysis of random compositions in the simplex. This assumption underlays almost all statistical methods and leads to spurious results when applied to CoDa.

Definition 3 Subcomposition. A subcomposition of a D -part composition $\mathbf{X}_D$ is a subvector of S parts, $S < D$,

$$\mathbf{X}_S = [X_1, X_2, \dots, X_S],$$

which support is the positive orthant of real space, $\mathcal{R}_+^S$, carrying relative information.

It is assumed that the same rules stated above for compositions hold for subcompositions. Thus, they represent parts of a (partial) whole and proportional vectors represent the same subcomposition. They are equivalence classes and any suitable representant of the class can be chosen. It is common to use a closed representation, the closure constant being usually 1, 100 or 10^6 . One frequent example in the geosciences is the representation of a three-part subcomposition of a geochemical analysis in a ternary diagram.

Compositional Data, Fig. 1 Compositional equivalence classes in 3D. The ray from the origin through B is the class which contains the equivalent points Q and F

Introduction

Historically, CoDa have been defined as vectors of positive components constraint by a constant sum or closure constant, usually 1, 100 or 10^6 . Nowadays, understanding CoDa as equivalence classes represented by one element of that class has broadened the concept. Available methods, designed to be scale invariant, allow us to analyze the data in such a way that the closure constant, if any, is not important.

Problems with the analysis of CoDa were first detected by Karl Pearson (1897), who coined the term *spurious correlation*. Awareness of these problems was kept alive by many authors in the geosciences. It was John Aitchison (1982) who put forward the log-ratio approach, opening the way to deal consistently with CoDa. He set the basic framework that allowed later to define the algebraic-geometric structure of the sample space of CoDa. This was published simultaneously by Billheimer et al. (2001) and by Pawlowsky-Glahn and Egozcue (2001). It was the clue to understanding that there is no solution to these problems under the assumption that compositional data are vectors in real space that obey the usual Euclidean geometry.

It can be shown mathematically that for raw data represented in the simplex (Eq. 2), i.e., closed or normalized to a constant, the covariance matrix necessarily is singular, has some non-zero and some negative entries, and is subcompositionally incoherent. To find subcompositions for which the sign of one or more covariances changes, it suffices to take the closed representant of the subcomposition consisting of those parts which have positive covariances. This shows that covariances of compositions are subject to nonstochastic controls, and this fact leads to the conclusion that they are spurious, and thus nonsensical.

Problems with raw CoDa were described extensively by Felix Chayes (1971). They appear because they are assumed to be points in D -dimensional real space endowed with the usual Euclidean geometry. This assumption does not guarantee subcompositional coherence, and the following issues appear: (1) the mathematical necessity of at least one non-zero covariance; (2) the bias towards negative covariances; (3) the singularity of the covariance matrix; and (4) the non-stochastic control, and thus description and interpretation, of the dependence between the variables under study.

Principles

John Aitchison (1982) introduced three principles, here called *Aitchison principles*, which should govern any compositional analysis.

Aitchison Principle 1. Scale Invariance

Two proportional vectors give the same compositional information. They represent the same composition

$$\begin{aligned}\mathbf{X}_D &= [X_1, X_2, \dots, X_D] \equiv \kappa \cdot \mathbf{X}_D \\ &= [\kappa \cdot X_1, \kappa \cdot X_2, \dots, \kappa \cdot X_D].\end{aligned}$$

Aitchison Principle 2. Subcompositional Coherence

A result for $X_i, X_j \in \mathbf{X}_S$ will not lead to a contradiction with a result obtained for $X_i, X_j \in \mathbf{X}_D$.

Aitchison Principle 3. Permutation Invariance

Results should be invariant if the order of the parts in the composition is changed.

The principles above were stated by Aitchison (1982) before the vector space structure of the sample space of CoDa was recognized. They were led by the idea that methods for CoDa should be consistent whichever path is followed. Considering CoDa as equivalence classes corresponds to the Aitchison Principle 1, while the Aitchison geometry of the simplex makes the requirements of the Aitchison Principles 2 and 3 unnecessary, as long as one works on orthonormal (Cartesian) coordinates.

The Sample Space of Compositional Data

The set of compositions represented by vectors subject to a constant sum is the D -part simplex,

$$\mathcal{S}^D = \left\{ [x_1, x_2, \dots, x_D] \in \mathcal{R}_+^D \mid x_i > 0, i = 1, 2, \dots, D; \sum_{i=1}^D x_i = \kappa \right\}, \quad (2)$$

with κ an arbitrary constant, usually 1, 100 or 10^6 . The simplex is usually taken as a representative of the sample space of CoDa. The closure operation (1) allows one to select the representative of an equivalence class in $\mathcal{S}^D$. The principle of scale invariance, mentioned above, is reflected in the selection of the simplex (Eq. 2); it excludes zero or negative values. This leads to the zero problem in CoDa, which is extensively addressed in Palarea-Albaladejo and Martín-Fernández (2015).

An important concept in CoDa analysis is subcompositional coherence. As mentioned above, a subcomposition is a vector that includes only some parts of the original composition. A subcomposition is in general normalized to a constant sum, like when three parts of a larger composition are plotted in a ternary diagram. Subcompositional coherence is then the requirement that

statements about parts in the original composition hold when a subcomposition is considered.

The Aitchison Geometry for CoDa

For $\mathbf{x}, \mathbf{y} \in \mathcal{S}^D$, $\alpha \in \mathcal{R}$, the following operations can be defined:

- Perturbation: $\mathbf{x} \oplus \mathbf{y} = \mathcal{C}[x_1 y_1, x_2 y_2, \dots, x_D y_D]$;
- Powering: $\alpha \odot \mathbf{x} = \mathcal{C}[x_1^\alpha, x_2^\alpha, \dots, x_D^\alpha]$;
- Inner product: $\langle \mathbf{x}, \mathbf{y} \rangle_a = \frac{1}{2D} \sum_{i=1}^D \sum_{j=1}^D \ln \frac{x_i}{x_j} \ln \frac{y_i}{y_j}$;

These operations generate a $(D - 1)$ -dimensional Euclidean vector space structure known as Aitchison geometry (Pawlowsky-Glahn and Egozcue 2001). The inner product has an associated norm

$$\|\mathbf{x}\|_a = \sqrt{\frac{1}{2D} \sum_{i=1}^D \sum_{j=1}^D \left(\ln \frac{x_i}{x_j} \right)^2},$$

and an associated distance:

$$d_a(\mathbf{x}, \mathbf{y}) = \sqrt{\frac{1}{2D} \sum_{i=1}^D \sum_{j=1}^D \left(\ln \frac{x_i}{x_j} - \ln \frac{y_i}{y_j} \right)^2}.$$

Perturbation, powering, and distance were already defined by Aitchison (1982). Perturbation is particularly interesting, as it can be interpreted in a very intuitive way as *linear filtering*. Also, any change in composition expressed as increasing or decreasing percentages of the parts is a perturbation as, for instance, a decrease of 3% implies multiplication by 0.97 of that part.

Linear Functionals on Compositions

In most CoDa analysis some real functions of compositions, called functionals, may have a special interest depending on the research questions. However, these functionals should be scale invariant to be consistent with the Aitchison principles. A functional ϕ is scale invariant if, for any composition $\mathbf{x}$ and any scalar $\mathbf{k}$, $\phi(k\mathbf{x}) = \phi(\mathbf{x})$. If the function is not scale invariant, equivalent compositions closed to a different constant κ give different results. For instance, the log ratios $\log(\text{Ca/Mg})$ and $\log(\text{Cl}/(\text{Ca} + \text{Mg}))$ in a water analysis do not depend on the units in which they are expressed, be it in mg/L or $\mu\text{g/L}$. In many cases, a linear behavior of functionals can be a convenient condition for functionals. This is $\phi(\alpha \odot (\mathbf{x} \oplus \mathbf{y})) = \alpha(\phi(\mathbf{x}) + \phi(\mathbf{y}))$. This linearity property assures that a change of units acts on the functional in the same way for mean values and that variability only changes with the square of the scaling factor α . Changing from mg/L to atoms/L in Ca and Mg consists of dividing both concentrations in

mg/L by the respective atomic weights which are, approximately, (40., 24.), respectively. This division of both elements and any other in the composition is a perturbation. If $\mathbf{x} = (\dots, \text{Ca}, \text{Mg}, \dots)$ and $\mathbf{y} = \mathcal{C}(\dots, 1/40., 1/24., \dots)$, then

$$\log \frac{\text{Ca mg/L}}{\text{Mg mg/L}} = \log \frac{\text{Ca atom/L}}{\text{Mg atom/L}} + \log \frac{y_{\text{Ca}}}{y_{\text{Mg}}},$$

$$y_{\text{Ca}} = \frac{1}{40.}, \quad y_{\text{Mg}} = \frac{1}{24.}.$$

Taking the values of $\log(\text{Ca/Mg})$ in mg/L across a sample, the average of the functional values changes summing the log ratio $\log(y_{\text{Ca}}/y_{\text{Mg}})$, and the variance remains unaltered. This recalls that a perturbation, in this case a change of units, is a shift in the simplex.

It is straightforward to check that the amalgamated log ratio $\log(\text{Cl}/(\text{Ca} + \text{Mg}))$ is nonlinear. Contrarily, consider the functional

$$\phi(\mathbf{x}) = \sum_{i=1}^D a_i \log x_i, \quad \sum_{i=1}^D a_i = 0,$$

called *log contrast*. All linear scale invariant log ratios have this form. Functionals like $\log(x_1/x_2)$, $\log(x_1/g_m(\mathbf{x}))$, and $\log(g_m(x_1, x_2)/g_m(x_3, \dots, x_D))$, where $g_m(\cdot)$ is the geometric mean of the arguments, are log contrasts.

Among log contrasts, the class of *balances* are of the form

$$B(\mathbf{x}_+/\mathbf{x}_-) = \sqrt{\frac{n_+ n_-}{n_+ + n_-}} \log \frac{g_m(\mathbf{x}_+)}{g_m(\mathbf{x}_-)}, \quad (3)$$

where $\mathbf{x}_+$ and $\mathbf{x}_-$ denote two groups of parts included in $\mathbf{x}$ and n_+ , n_- are the number of parts in the two groups, respectively. Sometimes, the square root in (3) is suppressed; the remaining log ratio of geometric means is a *non-normalized balance*.

The Principle of Working in Coordinates

It is well known that every $(D - 1)$ -dimensional Euclidean space is isometric to the $(D - 1)$ -dimensional real Euclidean vector space $\mathcal{R}^{D-1}$. This implies that *orthonormal coordinates* in $\mathcal{S}^D$ are elements of $\mathcal{R}^{D-1}$ that obey the usual Euclidean geometry; and, consequently, all available methods developed in $\mathcal{R}^{D-1}$ under the implicit or explicit assumption that the coordinates are orthonormal hold on orthonormal coordinates in $\mathcal{S}^D$. To apply this fact in practice, it suffices to realize that most statistical methods developed in $\mathcal{R}^{D-1}$ assume cartesian coordinates. However, some non-orthonormal coordinates have properties that made them historically relevant.

Non-Orthogonal Log-Ratio Representations

The following two non-orthogonal representations were introduced by Aitchison (1982):

Centered Log-Ratio (clr) Representation

For $\mathbf{x} \in \mathcal{S}^D$ and $g_m(\mathbf{x})$ the geometric mean of the parts in $\mathbf{x}$, it is defined as

$$\text{clr}(\mathbf{x}) = \left[\ln \frac{x_1}{g_m(\mathbf{x})}, \ln \frac{x_2}{g_m(\mathbf{x})}, \dots, \ln \frac{x_D}{g_m(\mathbf{x})} \right],$$

$$g_m(\mathbf{x}) = \left(\prod_{i=1}^D x_i \right)^{1/D}.$$

This representation is very useful for computational issues, as it has important properties:

- For $v_i = \ln \frac{x_i}{g(\mathbf{x})}$ it holds $\sum_{i=1}^D v_i = 0$.
- The clr is a bijection between $\mathcal{S}^D$ and the hyperplane $\mathcal{R}_0^D \subset \mathcal{R}^D$, that is, the plane in $\mathcal{R}^D$ such that for any $\mathbf{v} \in \mathcal{R}^D$, $\sum_{i=1}^D v_i = 0$.
- The clr inverse is

$$\mathbf{x} = \text{clr}^{-1}(\mathbf{v}) = \mathcal{C} \exp[v_1, v_2, \dots, v_D].$$

- The clr is an isomorphism, i.e., $\text{clr}(\mathbf{x} \oplus \mathbf{y}) = \text{clr}(\mathbf{x}) + \text{clr}(\mathbf{y})$ and $\text{clr}(\lambda \odot \mathbf{x}) = \lambda \cdot \text{clr}(\mathbf{x})$.
- The clr is isometric, i.e., $d_a(\mathbf{x}, \mathbf{y}) = d_e(\text{clr}(\mathbf{x}), \text{clr}(\mathbf{y}))$, where d_a stands for the Aitchison distance defined above, and d_e for the usual Euclidean distance.

Additive Log-Ratio (alr) Representation

For $\mathbf{x} \in \mathcal{S}^D$, it is defined as

$$\text{alr}(\mathbf{x}) = \left[\ln \frac{x_1}{x_D}, \ln \frac{x_2}{x_D}, \dots, \ln \frac{x_{D-1}}{x_D} \right],$$

where the part in the denominator can be any part in the composition. This representation has mainly historical interest, as it corresponds to a representation in oblique coordinates, which are not always easy to handle in computing Aitchison distances and orthogonal projections.

Both representations, clr and alr, are too easily associated with the compositional parts appearing in the numerators of the log ratio, thus suggesting a kind of identification. This association is a source of confusion and misinterpretation. In fact, the log ratios in both alr and clr involve more than a single part, thus favoring the false impression that the log-

ratio CoDa approach can deal with single parts when the relevant quantities are always scale-invariant ratios.

Orthogonal Log-Ratio Representations

They are based on the Euclidean vector space theory. The orthogonal projection of a vector on an orthonormal basis of the space generates orthonormal coordinates which fully represent the vector. The same ideas apply to the simplex where the vectors are now compositions.

Definition 4 Orthonormal basis. Compositions $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_{D-1}$ in $\mathcal{S}^D$ constitute an orthonormal basis if

$$\langle \mathbf{e}_i, \mathbf{e}_j \rangle_a = \langle \text{clr}(\mathbf{e}_i), \text{clr}(\mathbf{e}_j) \rangle = \delta_{ij},$$

where the Kronecker delta δ_{ij} is equal to 0 when $i \neq j$ and equal to 1 for $i = j$.

Definition 5 Basis contrast matrix. It is the $\text{clr}(D-1, D)$ matrix of the basis:

$$\Psi = \begin{pmatrix} \text{clr}(\mathbf{e}_1) \\ \text{clr}(\mathbf{e}_2) \\ \vdots \\ \text{clr}(\mathbf{e}_{D-1}) \end{pmatrix},$$

$$\Psi\Psi' = I_{D-1}, \quad \Psi'\Psi = I_D - (1/D)\mathbf{1}_D'\mathbf{1}_D$$

Coordinates of a composition $\mathbf{x}$ are obtained computing the Aitchison inner product of $\mathbf{x}$ with each of the elements of an orthonormal basis, $x_i^* = \langle \mathbf{x}, \mathbf{e}_i \rangle_a$, and the expression of the original composition in terms of orthonormal coordinates leads to $\mathbf{x} = \oplus_{i=1}^{D-1} x_i^* \odot \mathbf{e}_i$. The function (olr) that assigns orthonormal coordinates to a composition is one to one.

Originally, olr coordinates were known as *isometric log-ratio coordinates* (ilr) (Egozcue et al. 2003), but this concept was confusing, as, e.g., the clr coordinates are isometric but not orthonormal, while any orthonormal system of coordinates in $\mathcal{S}^D$ endowed with the Aitchison geometry is isometric (see discussion Egozcue and Pawłowsky-Glahn 2019a, b).

Properties of an Orthonormal Representation

The olr: $\mathcal{S}^D \rightarrow \mathbb{R}^{D-1}$ defined through an orthonormal basis $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_{D-1}$ in $\mathcal{S}^D$ as $\text{olr}(\mathbf{x}) = \mathbf{x}^* = \text{clr}(\mathbf{x}) \cdot \Psi'$, with inverse $\text{olr}^{-1}(\mathbf{x}^*) = \mathbf{x} = \mathcal{C}(\exp(\mathbf{x}^*\Psi))$, is an **isometry**, that is,

- $\text{olr}(\alpha \odot \mathbf{x}_1 \oplus \beta \odot \mathbf{x}_2) = \alpha \cdot \text{olr}(\mathbf{x}_1) + \beta \cdot \text{olr}(\mathbf{x}_2) = \alpha \cdot \mathbf{x}_1^* + \beta \cdot \mathbf{x}_2^*$
- $\langle \mathbf{x}_1, \mathbf{x}_2 \rangle_a = \langle \text{olr}(\mathbf{x}_1), \text{olr}(\mathbf{x}_2) \rangle_e = \langle \mathbf{x}_1^*, \mathbf{x}_2^* \rangle_e$
- $\|\mathbf{x}\|_a = \|\text{olr}(\mathbf{x})\|, d_a(\mathbf{x}_1, \mathbf{x}_2) = d_e(\text{olr}(\mathbf{x}_1), \text{olr}(\mathbf{x}_2))$

where the subscripts e indicate that the operator is the ordinary Euclidean one.

There are different ways to build orthonormal coordinates within the Aitchison geometry for CoDa. One of them is based on principal component analysis of a dataset in its clr representation. The nonstandardized scores are olr coordinates and the loadings are a contrast matrix (Pawlowsky-Glahn et al. 2015). Consequently, the coordinates obtained in this way are data driven. Some further details are discussed in section “Exploratory CoDa Tools: Variation Matrix, Biplot, and CoDa-Dendrogram.”

Sequential Binary Partitions

A straightforward and intuitive way to define an orthonormal basis is through a sequential binary partition (SBP) of a generic composition. The construction is conveniently based on expert knowledge, but it can be done automatically or using specific algorithms, like the principal balances explained below. The procedure to define SBP (Pawlowsky-Glahn et al. 2015) is best explained with an example. Consider a composition $\mathbf{x} \in \mathcal{S}^5$. To define an SBP and to obtain the coordinates in the corresponding orthonormal basis proceed as illustrated in Table 1: The olr-coordinates assigned to each step of the partition are balances as defined in Eq. (3). For instance, the coordinate in step 3 in Table 1 would be $B(x_1/x_3, x_4)$ following the notation in that Equation.

Zeros

Most compositional datasets report zeros in some parts and cases. These zero values are incompatible with their transformation into log ratios, since infinite values would appear in the transformed dataset. Therefore, a preprocessing of the raw data is frequently required. However, the treatment of zeros needs a careful examination of their nature, and possibly some additional assumptions and decisions which are not based on the data themselves. This is a short description of the procedures to treat zeros. The interested reader is redirected to Palarea-Albaladejo and Martín-Fernández (2015) and references therein.

A first step is to decide the origin and nature of the zeros in the dataset.

At least, three classes can be distinguished: essential zeros, rounded zeros, and zeros from counts. *Essential zeros* are those which are due to the definition of the parts implying that, in certain circumstances, one or more parts are completely absent. An example is the use of land including for instance classes of forest and some types of agriculture. If a parcel is completely covered by forest, then there is no agriculture and each type of agriculture would be reported as 0%. These zeros are essential zeros. The treatment of essential zeros mainly consists in translating the presence-absence of zeros into a factor defining a subpopulation.

Rounded zeros and zero count can be processed in, at least, two ways: (A) the substitution of reported zeros by an imputed value, which is then processed as a regular compositional datum or, alternatively, (B) the zeros are thought as observations in a model in which these zero values are acceptable. Then, the analysis of such a model, consisting in the estimation of parameters, requires to know the likelihood of the parameters given the data including the zeros. The B methods avoid the explicit imputation of the zero values by estimating the parameters of the model.

Commonly, in A cases, a detection threshold is available or can be inferred to help the imputation. There are two classes of imputation, those where information only of the single part, which contains the zero, and of the corresponding detection limit is used; and those taking into account the relationship with other parts of the composition. If these imputation techniques are applied to counts, the imputation consists of a pseudo-count, frequently a value between 0 and 1.

A simple case is that of data in percentages, where also the detection limit is given in percentages. When a zero is present the multiplicative strategy of replacement consists of assigning a fraction of the detection limit to the reported zero, and then replacing all other observed data so that the resulting composition adds to 100.

A typical example of including the zeros in the estimation of parameters is the zero counts in a multinomial sampling. The goal is frequently to estimate the multinomial probabilities which are assumed positive. The multinomial likelihood

Compositional Data, Table 1 Example of SBP for a five-part composition. Four partition steps are necessary to complete the SBP; each one divides the active subcomposition into two groups of parts, marked

Step	x_1	x_2	x_3	x_4	x_5	Coordinate
1	+ 1	− 1	+ 1	+ 1	− 1	$y_1 = \sqrt{\frac{3 \cdot 2}{3+2}} \ln \frac{(x_1 \cdot x_3 \cdot x_4)^{1/3}}{(x_2 \cdot x_5)^{1/2}}$
2	0	+ 1	0	0	− 1	$y_2 = \sqrt{\frac{1 \cdot 1}{1+1}} \ln \frac{x_2}{x_5}$
3	+ 1	0	− 1	− 1	0	$y_3 = \sqrt{\frac{1 \cdot 2}{1+2}} \ln \frac{x_1}{(x_3 \cdot x_4)^{1/2}}$
4	0	0	+ 1	− 1	0	$y_4 = \sqrt{\frac{1 \cdot 1}{1+1}} \ln \frac{x_3}{x_4}$

with +1 or −1, respectively; nonactive parts are labeled with 0. The expression of balance coordinates corresponding to each step are in the right column

can include in a natural way zeros in the observation. A Bayesian estimation of multinomial probabilities provides an elegant solution of the problem. This class of approach typically requires the assumption of an underlying model for the observations.

The R-package *zCompositions* implements most of these imputation techniques (Palarea-Albaladejo and Martín-Fernández 2015, and references therein). However, the treatment of zeros in CoDa is not only a computational problem, but it requires a detailed examination of the character of the zeros and even a complete model for the whole dataset.

Exploratory CoDa Tools: Variation Matrix, Biplot, and CoDa-Dendrogram

Following the principle of working in coordinates (section “The Principle of Working in Coordinates”), compositional datasets can be represented in coordinates, preferably orthogonal, which are real variables. As a consequence, all exploratory tools devised for real variables can be applied to compositional log-ratio coordinates. However, there are at least three exploratory techniques that, although inspired in exploration of real variables, have characteristics that deserve particular attention. They are the variation matrix, the CoDa-biplot, and the CoDa-dendrogram. In order to illustrate the use of these tools, the Varanasi dataset described below is used.

Varanasi Dataset

The Varanasi dataset (VDS) (Olea et al. 2017) consists of concentration of ions dissolved in ground water sampled at 95 wells in the surroundings of Varanasi (India) on the two margins of the Ganga river. The following concentrations are reported: Fe($\mu\text{g/L}$), As($\mu\text{g/L}$), Ca(mg/L), Mg(mg/L), Na (mg/L), K(mg/L), HCO_3 (mg/L), SO_4 (mg/L), Cl(mg/L), NO_3 (mg/L), and F(mg/L). The data also reports the location

of the sample wells. Wells numbered 1 to 44 are placed on the left margin, and the remaining wells, from 45 to 95, on the right margin of the Ganga river.

The data matrix is denoted by $\mathbf{X}$; its columns are denoted by X_j , $j = 1, 2, \dots, D$ ($D = 11$ in VDS) and the rows containing a composition are denoted $\mathbf{x}_i$, where $i = 1, 2, \dots, n$ ($n = 95$ in VDS).

A first step in an exploration of a compositional dataset is often the computation of quantiles of its columns. This step is not important in a compositional data study except for detecting errors and/or the presence of zeros, and to have a first impression of the scale and units of the parts. In VDS, there are no zeros, but the initial values of Fe and As were given in $\mu\text{g/L}$, while the remaining elements are in mg/L . Although the compositional analysis can be performed on these nonhomogeneous units, Fe and As were divided by 1000 for translating them into mg/L . Note that such transformation is a perturbation.

Center and Variability

The *center* of a composition plays the role of the mean for real data. It is estimated as a perturbation-average along the data matrix

$$\text{cen}[\mathbf{X}] = \frac{1}{n} \odot \bigoplus_{i=1}^n \mathbf{x}_i,$$

where the big $\oplus$ is a repeated perturbation. The symbol *cen* denotes *sample center* and it is an estimator of the theoretical center. Table 2 shows the sample center of the VDS in mg/L . Those values are the geometric means of the columns of VDS provided that all compositional data (rows of $\mathbf{X}$) are given in homogeneous units. When all the data in the sample are closed to a constant κ , the resulting geometric means by columns should be closed to the same κ .

In statistical analysis of real data, variability of the sample is very often described by the sample covariance matrix or its

Compositional Data, Table 2 Sample center (first row in mg/L) and normalized variation matrix $[\tau_{ij}]$ of Varanasi data corresponding to the samples on the left margin of Ganga river. Normalized variations less than 0.2 are in boldface and marked with an asterisk

standardization, the (Pearson) correlation matrix. When dealing with compositional data these matrices are spurious (Aitchison 1986). They are useless and confusing for a further analysis. Alternatively, variability of a compositional dataset can be described by means of the variation matrix (Aitchison 1986). The *variation matrix* is a (D, D) matrix T whose entries are

$$t_{ij} = \text{var} \left[\log \frac{X_i}{X_j} \right], \quad i, j = 1, 2, \dots, D.$$

The entries $t_{ii} = 0$, as there is no variability in $\log(X_i/X_i)$. When t_{ij} is small, near to zero, it suggests linear association between the parts X_i and X_j (Egozcue et al. 2018). In fact, if $X_i \simeq aX_j$, for some $a \in \mathcal{R}$, then $t_{ij} \simeq 0$, that is, they are proportional or nearly so.

Large values of t_{ij} point out the main sources of variability in the sample. In Aitchison (1986), the sample *total variance* is defined as the average entry of T , that is,

$$\text{totvar}[\mathbf{X}] = \frac{1}{2D} \sum_{i=1}^D \sum_{j=1}^D t_{ij}.$$

The total variance can be also expressed using the clr and olr representations of the sample. It can be shown that

$$\text{totvar}[\mathbf{X}] = \sum_{i=1}^D \text{var}[\text{clr}_i(\mathbf{X})] = \sum_{i=1}^{D-1} \text{var}[\text{olr}_i(\mathbf{X})], \quad (4)$$

where the last term points out that the sample total variance is the trace of the sample covariance matrix of the olr coordinates, thus matching the terminology in statistical analysis of real data.

The values in T strongly depend on the number of parts, D , and the total variance. In order to interpret and compare the values in T , some normalizations have been proposed. For instance, if the total variance were spread over all non-null entries of T , the values would be $2D\text{totvar}[\mathbf{X}]/(D(D-1))$. Comparing this value with t_{ij} , a normalized variation is

$$\tau_{ij} = \frac{D-1}{2\text{totvar}[\mathbf{X}]} \cdot t_{ij}, \quad \sum_{i=1}^D \sum_{j=1}^D \tau_{ij} = (D-1)D$$

where values of $\tau_{ij} \geq 1$ suggest no linear association and $\tau_{ij} < 1$ indicates possible association (Pawlowsky-Glahn et al. 2015). In practice, $\tau_{ij} > 0.2$ corresponds to very poor linear associations. It is worth noting that the approximate linear association between two parts depends on the subcomposition considered (Egozcue et al. 2018). Table 2 shows the sample center and the normalized variation matrix for the data from the left margin of the Ganga river. The ion bicarbonate is suggested to be linearly associated with F and As. These evidences of association are not apparent in the right margin.

Compositional Biplot

The singular value decomposition (SVD) is an algebraic technique for decomposition of data matrices. It is routinely used in principal component analysis. When dealing with compositional data the SVD is applied to the centered $\text{clr}(\mathbf{X})$, that is to $\text{clr}(\mathbf{X} \ominus \text{cen}[\mathbf{X}])$, where $\text{cen}[\mathbf{X}]$ is perturbation-subtracted from each row of $\mathbf{X}$. The SVD results in

$$\text{clr}(\mathbf{X} \ominus \text{cen}[\mathbf{X}]) = U \Lambda V^T,$$

where $\Lambda = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_{D-1}, 0)$ contains the singular values ordered from larger to smaller; U is an (n, D) matrix and V is a (D, D) matrix. The last singular value is 0 due to the fact that the rows of the decomposed matrix add up to 0, as pointed out above, after the definition of the clr. This means that the last 0 in Λ , and the last columns of U and V , can be suppressed. After this suppression and maintaining the same notation, Λ , U , and V are $(D-1, D-1)$, $(n, D-1)$, $(D, D-1)$ matrices, respectively (Pawlowsky-Glahn et al. 2015). The main property of V is that it is orthogonal, i.e., $V^T V = I_{D-1}$. Therefore, $\Psi = V^T$ is a contrast matrix and $U\Lambda = \text{olr}(\mathbf{X} \ominus \text{cen}[\mathbf{X}])$. The columns of V (rows of Ψ) contain the clr's of the elements of an orthonormal basis of the simplex, and the rows of $U\Lambda$ are the (centered) olr coordinates of the compositional dataset. Also $U^T U = I_{D-1}$ and, consequently, the singular values are proportional to the standard deviations of the olr coordinates. Furthermore, $\sum_{i=1}^{D-1} \lambda_i^2 = n \text{totvar}[\mathbf{X}]$, where the centering of $\mathbf{X}$ can be suppressed, since centering does not affect the total variance. These properties allow the simultaneous plotting of the centered clr variables and of the compositions in the dataset, represented by their olr coordinates. Commonly, two olr coordinates are chosen for the plot, say the first and the second coordinates. For such a projection the proportion of total variance shown in the plot is $(\lambda_1^2 + \lambda_2^2)/n \text{totvar}[\mathbf{X}]$. Superimposed to the olr coordinates, the clr of the vectors of the basis (columns of V) can be plotted as arrows. As these vectors are unitary, the length in the plot indicates the orthogonal projection on the coordinates chosen for the biplot. This kind of plot is called *form compositional biplot*. It is appropriate to look for features of the data and to their (Aitchison) interdistances projected onto a two-dimensional plot.

However, the most frequent biplot is the *covariance compositional biplot*. The compositions in the dataset are represented by the standardized coordinates in U (called scores in a standard principal component analysis); simultaneously, the arrows to the columns of ΛV are plotted, so that the length of the arrows are proportional to the standard deviation of the clr variables, provided the projection represents a good deal of the total variance. The main interpretative tools are the lengths and directions of the links between the heads of two arrows. These lengths, up to a good projection,

are proportional to the standard deviations of the log ratios between the parts labeling the corresponding arrows. That is, they are approximately proportional to the square root of the elements in the variation matrix.

Figure 2 shows covariance biplots for VDS. The corresponding form biplots are quite similar and are not shown. The left panel corresponds to the projection on the first and second principal coordinates, but this projection only represents 50% of the total variance. The right panel shows the projection on the first and third principal coordinates, this latter contributing an additional 15% of the total variance. The sampling points on the left margin of the river are plotted in red and those on the right margin in green. In the two projections the left margin points appear less disperse than those of the right margin. However, the left margin sample appears mixed within the right margin in both projections. In fact, the total variance of the joint sample is 7.61 while the total variance for the left and right margin samples are, respectively, 5.14 and 8.28.

In both projections shown in Fig. 2, the links between the arrows from the apexes of As, Fe, and Ca to those of Mg, K, and SO_4 are approximately parallel to the first principal axis. This means that the fraction of total variance of the first principal coordinate comes from log-ratio variances between elements from one from each group. Also, this suggests that the variance of the balance $B(\text{Mg}, \text{K}, \text{SO}_4/\text{As}, \text{Fe}, \text{Ca})$ can be similar (but less than) the variance of the first principal coordinate. Additionally both biplots suggest that the two margins of the river are distinguishable in mean by this first principal coordinate or by its proxy, the mentioned balance. Many observable features in the biplots are also identifiable in the variation matrices in a more quantitative way. For this reason

the CoDa-biplot can be considered one of the most powerful tools in the exploration of CoDa. More detailed explanations can be found in Pawlowsky-Glahn et al. (2015) and references therein.

Compositional Dendrogram

The principle of working on coordinates proposes the statistical analysis of olr coordinates as real coordinates. This is valid for exploratory purposes as well. Consequently, the standard description of sample mean, quantiles, and variances of coordinates should be accompanied of a definition of the basis that define the coordinates. In the case in which the basis is defined by an SBP and the coordinates are balances, the basis can be represented by a tree structure or dendrogram. An exploration based on mean and variances of the balance coordinates can be shown on the dendrogram structure, thus providing a powerful interpretation of the balance coordinates. Figure 3 is a CoDa-dendrogram for the VDS. A partition of the composition has been chosen using the principal balances technique (Martín-Fernández et al. 2018) which tries to mimic the principal component analysis using balances. The elements in a CoDa-dendrogram are:

- (1) The tree which reproduces the SBP selected.
- (2) The horizontal bars, which are equally scaled in the interval $(-7, 7)$ in Fig. 3, representing an interval for the corresponding balance in the tree. Their length in the plot is meaningless and only corresponds to the spacing of the labels. The anchoring of vertical bars on the horizontal ones points out the mean of the balance in the mentioned scale.

Compositional Data, Fig. 2 Covariance biplots for VDS. Left margin, red points; right margin, green points. Projection on first-second (left panel) and first-third (right panel) principal coordinates

Compositional Data, Fig. 3 CoDa dendrogram for VDS. The SBP corresponds to principal balances. Black tree: joint sample; red tree: left margin sample; green tree: right margin sample

- (3) The length of vertical full lines is proportional to the variance associated with the balance, thus reproducing the decomposition of the total variance by olr coordinates in Eq. (4).

The CoDa-dendrogram can be completed with some boxplots following the scale of the horizontal bars (not shown in Fig. 3). When there are two or more subpopulations, like in the present case the left and right margins of the Ganga river, the trees corresponding to each subpopulation can be superimposed. In Fig. 3, the black tree corresponds to the joint sample, whereas the red and the green trees represent the data in the left and right margins, respectively. This allows the comparison of mean values and variances of the subpopulations, a kind of visual ANOVA for each coordinate.

If the goal is to identify features that distinguish the left and right margins of the river, Fig. 3 reveals that the sample mean of balance $B(\text{Mg}, \text{K}, \text{SO}_4/\text{As}, \text{Fe}, \text{Ca})$ shows the largest difference for the two margins. Simultaneously, the CoDa-dendrogram indicates that the variance of this balance in the right margin is larger than in the left margin, a fact also shown in Fig. 2. Also, the variance of balance $B(\text{F}/\text{HCO}_3)$ is similar in both margins, and the variance is smaller than that of other balances, thus suggesting a linear association between F and HCO_3 . It should be remarked that the CoDa-dendrogram is strongly dependent on the SBP selected, but is extremely useful when the goal of the exploration is clearly stated and expert knowledge about the problem is available.

Software for CoDa

Several software packages are available for the analysis of compositional data following a log-ratio approach, among others the following:

1. **CoDaPack**: This is a user-friendly, stand-alone, freeware, developed by the Research Group on Compositional Data Analysis from the Computer Science, Applied Mathematics, and Statistics Department of the University of Girona (UdG). It can be downloaded from the web. This software was developed as support for short courses and is not a complete statistical package. Nevertheless, the most recent version allows a direct link to R, opening a wide range of opportunities (Comas-Cufí and Thió-Henestrosa 2011).
2. **R-package “compositions”**: This is a very complete package including most procedures available for CoDa. It is conceived for scientists familiar with the mathematical foundations of CoDa and R-programming. An introduction to this package and CoDa procedures is van den Boogaart and Tolosana-Delgado (2013).
3. **R-package “robCompositions”**: Originally implementing robust statistical procedures in CoDa, it grew to incorporate other CoDa procedures. Many of its features are described in Filzmoser et al. (2018).
4. **R-package “zCompositions”**: Directed to the analysis of different kinds of zeros and missing data appearing in CoDa datasets. Useful in preprocessing of most CoDa problems (Palarea-Albaladejo and Martín-Fernández 2015).

Conclusions

CoDa represents the paradigm of what can go wrong if a methodology is applied to data that do not comply with the assumptions on which the methodology is based. A consistent and coherent solution for CoDa came from recognizing the Euclidean-type structure of the sample space, nowadays known as Aitchison geometry. In the framework of this geometry coordinates can be defined that allow for the application of standard methods. It is still a very active and open field of research, as many research questions call for the development of appropriate models which comply with the log-ratio approach.

Books on Compositional Data Analysis

The Aitchison (1986) book is the first book on compositional data analysis. It is seminal for most of procedures in CoDa within the log-ratio approach. After the recognition of the Aitchison geometry of the simplex and of the conception of compositions as equivalence classes, a number of books covering all theory, applications, and software have been published:

- Buccianti et al. (2006), made of contributed chapters. Most chapters are applications of compositional data to geological cases, but it also contains theoretical elements.

- Pawlowsky-Glahn and Buccianti (2011), made of contributed chapters. It includes chapters collecting advances in theoretical issues related to CoDa analysis and related methodologies. Also a variety of applications are collected. It represents the state of the art in 2011.
- van den Boogaart and Tolosana-Delgado (2013), mainly oriented to introducing the R-package *compositions* and its use, also contains valuable descriptions of the CoDa theory.
- Pawlowsky-Glahn et al. (2015), initially conceived as lecture notes, is a textbook introducing most methods dealing with CoDa.
- Filzmoser et al. (2018) is a guide through CoDa statistical applications with theoretical hints and R-programming linked to the R-package *rob-Compositions*.
- Greenacre (2018) presents some CoDa methodologies illustrated with examples developed with software in R.

Definition

Process – A phenomenon that is defined within a coordinate space with a valid metric. Processes can be defined by the geochemical composition of a material (e.g., mineral), combinations of minerals (rocks), or measures of rock assemblage properties including magnetic properties, electroconductivity, and density. Coherence in the form of geospatial continuity or an ordered and distinctive framework defines patterns that can be interpreted in a geochemical/geological context and subsequently tested as processes. Examining geochemical data on an element-by-element basis has been reviewed by McKinley et al. (2016). Multielement geochemical surveys provide insight into geochemical processes through the use of multivariate statistical methods.

Metric – A measure of a process within a coherent coordinate space. Different processes have different coordinate spaces and hence, different metrics. Commonly used metrics are derived from Hilbert spaces that are intrinsically orthonormal. The most commonly known metric is the Euclidian space. Non-orthogonal bases can also be used to discover/display features of a process. Such bases occur when

compositional data are in raw form or transformed using the additive logratio (alr), centered logratio (clr), isometric logratio (ilr), or pivot coordinates (pvc) Aitchison (1986), Egozcue et al. (2003). Despite the non-orthogonality of these bases, meaningful interpretations can be derived from the data and used to validate known processes or identify new processes (Greenacre et al. 2022). The relationships between the elements of geochemical data are controlled by “natural laws” (Aitchison 1986). In the case of inorganic geochemistry that law is stoichiometry, which governs how atoms are combined to form minerals, and thereby defines the structure within the data.

In the case of compositional data, additional measures are required in order to overcome the constant sum (closure) problem. Elements or oxides of elements are generally expressed as parts per million (ppm), parts per billion (ppb), weight percent (wt%, or simply %), or some other form of “proportion.” When data are expressed as proportions, there are two important limitations: first the data are restricted to the positive number space and must sum to a constant (e.g., 1,000,000 ppm, 100%), and second when one value (proportion) changes, one or more of the others must change too to maintain the constant sum. This problem cannot be overcome by selecting sub-compositions so that there is no constant sum. The “constant sum,” or “closure,” problem results in unreliable statistical measures. The use of ratios between elements, oxides, or molecular components that define a composition is essential when making comparisons between elements in systems such as igneous fractionation. The use of logarithms of ratios, or simply logratios, is required when measuring moments such as variance/covariance.

Depending on the data type, other metrics can be used, which can be: nominal, binary, ordinal, count, time, and interval.

Each of these metrics defines different ways of expressing the relationships between the variable (elements) and the observations (analyses). From a Process Discovery perspective, different metrics can assist in the identification of different processes.

The following coordinate spaces are common in the field of data analytics for geochemistry:

- Principal Component Analysis (PCA) – Jolliffe (1986)
- Independent Component Analysis (ICA) – Comon (1994)
- Multidimensional Scaling (MDS) – Cox (2001)
- Minimum-maximum Autocorrelation Factor Analysis (MAF) – Switzer and Green (1984)
- t-distributed Stochastic Neighbor Embedding (t-SNE) – van der Maaten and Hinton (2008)
- Uniform Manifold Approximation and Projection (UMAP) – McInnes et al. (2020)

Other metrics can be used to measure associations between variables and observations.

A two-step approach is recommended for evaluating multielement geochemical data. In the first “process discovery” step, patterns, trends and associations between observations (sample sites) and variables (elements) are extracted. Geospatial associations are also a significant part of process discovery. Patterns and/or processes that demonstrate geospatial coherence likely reflect an important geological/geochemical process.

Following process discovery, “process validation” is the step in which the patterns or associations are statistically tested to determine if these features are valid or merely coincidental associations. Patterns and/or associations that reveal lithological variability in surficial sediment, for instance, can be used to develop training sets from which lithology can be predicted in areas where there is uncertainty in the geological mapping and/or paucity of outcrop. Patterns and associations that are associated with mineral deposit alteration and mineralization may be predicted in the same way. In low-density geochemical surveys, where processes such as those related to alteration and mineralization are generally under-sampled, it may be difficult to carry out the process validation phase relating to these processes.

Censored Data

Quality assurance and quality control of geochemical data require that rigorous procedures be established prior to the collection and subsequent analysis of geochemical data. This includes the use of certified reference standards, randomization of samples, and the application of statistical methods for testing the analytical results. Historical accounts of Thompson and Howarth plots, for analytical results, can be found in Thompson and Howarth (1976a, b).

Geochemical data reported at less than the lower limit of detection (censored data) can bias the estimates of mean and variance; therefore, a replacement value that more accurately reflects an estimate of the true mean is preferred. Replacement values for censored geochemical data can be determined using several methods. The *lrEM* function from the R Computing Environment, *zCompositions* package (Palarea-Albaladejo et al. 2014) is suitable to use for estimating replacement values. Values greater than the upper limit of detection (ULD) can also be adjusted, based on a linear regression model formed by the uncensored data below the ULD.

Process Discovery

The following provides a few ways that processes can be discovered in multielement geochemical survey data.

Multivariate Data Analysis Techniques

The usefulness of multivariate data analysis methods applied to geochemical data has been well documented. An interpretation of the relationships of 30 elements is almost impossible without applying some techniques to simplify the relationships of elements and observations. Multivariate data analysis techniques such as those listed above provide numerical and graphical means by which the relationships of a large number of elements and observations can be studied Grunsky (2010) and Grunsky and Caritat (2019). These techniques typically simplify the variation and relationships of the data in a reduced number of dimensions, which can often be tied to specific geochemical/geological processes.

Incorporation of the spatial association with multielement geochemistry involves the computation of auto- and cross-correlograms or co-variograms. This field of study falls into the realm of geostatistics, which is not covered in this contribution. Multivariate geostatistics, which incorporates both the spatial and inter-element relationships, has been studied by only a few. Grunsky (2012) provides details on several approaches to account for geospatial variation in multivariate data.

The discovery of processes is typically carried out through the use of unsupervised methods within a multivariate framework in which patterns of the variables are detected. Unsupervised methods are also known as “unsupervised learning.” Pattern recognition depends on two essential elements: a reduction of noise in the system (signal/noise ratio) and the application of these methods at an appropriate scale of measurement (metric). The metric of measurement can be either linear or nonlinear. Linear metrics are useful for detecting patterns that are defined by linear processes such as stoichiometric control in mineralogy or linear combinations of minerals that comprise various rock types. Nonlinear processes may reflect processes that cannot be modeled using a linear metric. Geological processes such as mineral sorting through gravitational processes or chaotic processes (storm events) can be nonlinear. The scale of the metric may have an influence on the ability to determine linear/nonlinear processes. A multivariate approach is an effective way to start the process discovery phase. Linear combinations of elements that are controlled by stoichiometry may occur as strong patterns, while random patterns and/or under-sampled processes show weak or uninterpretable patterns.

An essential part of the process discovery phase is a suitable choice of coordinates to overcome the problem of closure. The centered logratio (clr) transformation (Aitchison 1986) is a useful transformation for evaluating geochemical data. Discovery of persistent and meaningful patterns enables the establishment of training sets for specific models to carry out process prediction. Models can include geology, mineral occurrences/prospects/deposits, soil types, and anthropogenic domains.

Statistical measures applied to geochemical data typically reveal linear relationships, which may represent the

stoichiometry of rock-forming minerals and subsequent processes that modify mineral structures, including hydrothermal alteration, weathering, and water–rock interaction. Physical processes such as gravitational sorting can effectively separate minerals according to the energy of the environment and mineral/grain density. Mineral chemistry is governed by stoichiometry and the relationships of the elements that make up minerals are easily described within the simplex, an n -dimensional composition within the positive real number space. It has long been recognized that many geochemical processes can be clearly described using element/oxide ratios that reflect the stoichiometric balances of minerals during formation (e.g., Pearce 1968). Geochemical data, when expressed in elemental or oxide form, can be a proxy for mineralogy. If the mineralogy of a geochemical data set is known, then the proportions of these elements can be used to calculate normative minerals.

Comprehension of the patterns that are revealed in process discovery include a wide range of graphics and tables. The relative relationships between variables and observations can be observed through the different multivariate coordinate systems generated by metrics including:

- Principal Component Analysis (PCA)
- Independent Component Analysis (ICA)
- t -distributed Stochastic Neighbor Embedding
- Minimum/Maximum Autocorrelation Factor analysis (MAF)
- Multidimensional Scaling (MDS)
- Self-Organizing Maps (SOM)
- Neural Networks (NN)
- Random Forests (RF)
- Blind Source Separation
- Hierarchical/nonhierarchical/model-based clustering
- Fractal/Multi-fractal analysis

From a process discovery perspective, patterns generated by these coordinate systems that show geospatial coherence and/or positive/negative associations between the variables, may be useful in describing processes. The commonly used principal component coordinates of clr-transformed data are orthonormal (i.e., statistically independent) and can reflect linear processes associated with stoichiometric constraints.

Fractal Methods

Fractal mathematics is now commonly used in the geosciences. Cheng and Agterberg (1994), Cheng and Zhao (2011) showed how fractal methods can be used to determine thresholds of geochemical distributions on the basis of spatial patterns of abundance. Where the concentration of a particular component per unit area satisfies a fractal or multifractal model, the area of the component follows a power law relationship with the concentration. This can be expressed mathematically as:

$$A(\rho \leq v) \propto \rho^{-\alpha_1} \quad A(\rho > v) \propto \rho^{-\alpha_2}$$

where $A(\rho)$ denotes an area with concentration values greater than a contour (abundance) value greater than ρ . This also implies that $A(\rho)$ is a decreasing function of ρ . If v is considered the threshold value then the empirical model shown above can provide a reasonable fit for some of the elements.

In areas where the distribution of an element represents a continuous single process (i.e., background) then the value of α remains constant. In areas where more than one processes have resulted in a number of superimposed spatial distributions, there may be additional values of α defining the different processes.

The use of power-spectrum methods to evaluate concentration-area plots derived from geochemical data has also been shown by Cheng et al. (2000), whereby the application of filters and patterns can be detected related to background and noise, thus enabling the identification of areas that are potentially related to mineralization.

Visualizing the Coordinates and Elemental Associations of a Multivariate Metric

The transformation of the logratio coordinates can be visualized in the transformed metric space and the geographic domain. Some of the transformations permit the calculation and visualization of the variables with the observations.

An important part of determining variable significance is the measure of variance accounted by each component (dimension).

- Principal Component Biplots
- Minimum-Maximum Autocorrelation Biplots

Exploring data geospatially involves the use of coordinate system, in either a geodetic or orthogonal grid/metric. Coordinate systems generated by methods such as MAF include measures of geospatial association (Mueller et al. 2020). Geospatial signatures derived from variables that have positive/negative associations over a geospatial domain enhance the geospatial aspect of multivariate associations.

The process of principal component analysis involves choosing the appropriate metric (i.e., logcentered transform) from which eigenvalues/eigenvectors are computed using singular value decomposition. The resulting eigenvalues, plotted as a “screeplot,” indicates how much “structure” is in the data. Principal component biplots display the relative relationships between the observations (principal component scores) and the variables (principal component loadings). Biplots can reveal much information about the relative relationships between the variables and the sample population. The resulting principal components can also be plotted in the geospatial domain, whereby the principal component patterns can be visually assessed in terms of the geospatial relationships between geological/geochemical processes. Areas of

contiguous zones of similar principal component scores can show geospatial patterns that define the “geospatial coherence” of the data in a geographic sense.

Geospatial Coherence

Multivariate coordinate systems have coordinates based on metrics of the variables (elements) and the observations (geochemical analyses). Different coordinate systems display different relationships of the data. These coordinate systems provide insight into the discovery of processes. For geospatial geochemical data, geospatial coherence is defined as both local and regional continuity of a response based on geostatistical methods such as semi-variograms.

If a geospatial rendering of a principal component shows no spatial coherence (i.e., no structure, or a lot of “noise”), then it is likely that the image will be difficult to interpret within a geological context. The most effective way to test this is through the generation and modeling of semi-variograms that describe the spatial continuity of a specific class based on prior or posterior probabilities (PPs), which are described below. If meaningful semi-variograms can be created, then geospatial maps of PPs can be generated through interpolation using the kriging process. Maps of PPs may show low overall values but still be spatially coherent. This is also reflected in the classification accuracy matrix that indicates the extent of classification overlap between classes. Geospatial analysis methodology described by the “gstat” package (Pebesma 2004) in R can be used to generate the geostatistical parameters and images of the PCs and PPs from kriging.

If the spatial sampling density appears to be continuous then it may be possible to carry out spatial prediction techniques such as spatial regression modeling and kriging. A major difficulty with the application of spatial statistics to regional geochemical data is that the data seldom exhibit stationarity. Stationarity means that the data has some type of location invariance, that is, the relationship between any sets of points are the same regardless of geographic location. This is seldom the case in regional geochemical datasets. Thus, interpolation techniques such as kriging must be applied cautiously, particularly if the data cover several geochemical domains in which the same element has significantly different spatial characteristics.

Evaluation of the variogram or the autocorrelation plots can provide insight about the spatial continuity of an element. If the autocorrelation decays to zero over a specified range, then this represents the spatial domain of a particular geological process associated with the element. Similarly, for the variogram, the range represents the spatial domain of an element, which reaches its limit when the variance reaches the “sill” value, the regional variance of the element. Theoretically, at the origin, the variance should be zero at lag zero. However, typically, an element may have a significant degree of variability even at short distances from neighboring points. This variance is termed the nugget effect.

Skill, knowledge, and experience are required to effectively use geostatistical techniques. It requires considerable effort and time to effectively model and extract information from geospatial data. The benefits of these efforts are a better understanding of the spatial properties of the data, which permits a more effective predictive estimate of geochemical trends. However, they must be used and interpreted with the awareness about problems with techniques of interpolation and the spatial characteristics of the data.

Recognizing Rare Events – Under-Sampled Processes in Principal Component Analysis

In regional geochemical surveys, the sample design is not optimally suited for the recognition of geological processes that have small geospatial footprints such as a mineral deposit. Thus, sites that are associated with mineral deposits are under-sampled, relative to the dominant processes defined by background lithologies. A principal component analysis may identify these “rare event” processes in the lesser eigenvalues/eigenvectors. Examination of biplots and geospatial plots of these lesser components can help identify mineral exploration targets or zones of contamination.

Process Validation – Testing Models Derived from Process Discovery

Process Validation – Process validation is the statistical measure of the likelihood of a given process as defined by discovery or by definition. When processes are defined by discovery, as described above, or by training sets defined by other means, the application of process validation provides a statistical measure of uniqueness of the process.

Using different multivariate coordinate systems (metrics), geochemical data can be classified using a variety of classification methods. The combination of coordinate systems and measures of proximity for classification results in a range of predictions. In a multivariate normal dataset, the results of the different combinations of coordinate systems and classifications can be similar. In datasets where there are multiple and distinct processes, the results may vary widely and provide different interpretations.

Classification can be carried out as a binary or multi-class process. For many geoscience applications that use multi-element geochemical data, multi-class classification studies are more common.

Bayesian methods produce predictive probabilities that are based on prior probabilities and are used in many classification algorithms.

A non-exhaustive list of classification/prediction methods include:

- Quadratic Discriminant Analysis (QDA)
- Logistic Regression (LR)
- Neural Networks (NN)
- Support Vector Machines (SVM)
- Boosting
- Classification and Regression Trees (CART)

Process validation is the methodology used to verify that a geochemical composition (response) reflects one or more processes. These processes can represent lithology, mineral systems, soil development, ecosystem properties, climate, or tectonic assemblages. Validation can take the form of an estimate of likelihood that a composition can be assigned membership to one of the identified processes. This is typically done through the assignment of class identifier or a measure of probability. Training sets contain the classes used to build a prediction model. The proportion of each class relative to the sum of all of the classes is termed the prior probability. After the application of the prediction model to the training set, and/or the test dataset, for each observation, there is list of proportional values of each class, which are termed the posterior probabilities (PP).

A critical part of process validation is the selection of variables that produce an effective classification. This requires the selection of variables that maximize the differences between the various classes and minimizes the amount of overlap due to noise, unrecognized or under-sampled processes in the data. As stated previously, because geochemical data are compositional in nature, the variables that are selected for classification require transformation to logratio coordinates. The alr or ilr are both effective for the implementation of classification procedures. The clr-transform is not suitable because the covariance matrix of these coordinates is singular. However, analysis of variance (ANOVA) applied to clr-transformed data enables the recognition of the compositional variables (elements) that are most effective at distinguishing between the classes. Choosing an effective alr-transform (choice of suitable denominator) or balances for the ilr-transform can be challenging and requires some knowledge and insight about the nature of the processes being investigated. The choice of a suitable divisor for the alr transform can be based on prior knowledge of the processes that involve specific elements. ANOVA applied to the PCs derived from the clr-transform has been shown to be highly effective at discriminating between the different classes. Typically, the dominant PCs (PC1, PC2, ...) commonly identify dominant processes and the lesser components (PCn, PCn-1, ..., where n is the number of variables) may reflect under-sampled processes or noise. The use of the dominant components can be interpreted as a technique to increase the signal/noise ratio and result in a more effective classification using only a few variables. Classification results can be expressed as direct class assignment or posterior probabilities (PPs) in the form of forced class allocation, or as class typicality. Forced

- Random Forests (RF)
- Linear Discriminant Analysis (LDA)

class allocation assigns a PP based on the shortest Mahalanobis distance of a compositional observation from the compositional centroid of each class. Class typicality measures the Mahalanobis distance from each class and assigns a PP based on the F-distribution. This latter approach can result in an observation having a zero PP for all classes, indicating that its composition is not similar to any of the compositions defined by the class compositional centroids.

The application of a procedure such as LDA can make use of cross validation procedures, whereby the classification of the data is repeatedly run based on random partitioning of the data into a number of equal sized subsamples. One subsample is retained for validation and the remaining subsamples are used as training sets. Classification accuracies can be assessed through the generation of tables that show the accuracy and errors measured from the estimated classes against the initial classes in the training sets used for the classification.

Class imbalance occurs when there is a disproportionate number of samples for the different classes being considered in a model. For example, in predictive lithology study, for the creation of a training set, there may be large number of observations that represent granitic rocks and a small number of samples that reflect volcanic rocks. This class imbalance can affect the resulting model from many of the classification methods. Class imbalance can be adjusted using methods such as the Synthetic Minority Oversampling Technique (Hariharan et al. 2017).

Example of Process Discovery and Process Prediction of Mineral Resource Potential Using Geochemical Survey Data

Regional geochemical survey data (Fig. 1) from southern British Columbia, Canada were studied for the potential of

Computational Geoscience, Fig. 1 Location map of stream sediment sampling sites (black dots) overlying a map of the regional geology. (From Grunsky and Arne 2020, Fig. 1)

discovering/prediction specific types of mineral deposits (Grunsky and Arne 2020), based on mineral deposit models that have been developed for the province (BC Geological Survey 1996). The study integrated the regional geochemical survey with a mineral occurrence database (MINFILE) comprised of active mines, past producers, developed prospects, prospects, occurrences, and anomalies (BC Geological Survey 2019) as seen in Fig. 2. Each mineral occurrence was assigned a specified mineral deposit model. The mineral occurrences are not colocated with the regional stream sediment survey data. Thus, based on the distance between a stream sediment sampling site and a mineral occurrence (Fig. 3), the attributes of the mineral occurrence were assigned to the stream sediment sample site. If the distance between the two sites exceeded 3000 m, no assignment was made and the mineral deposit model attribute was classed as “unknown.” Additionally, if the MINFILE record was identified as a “showing” and the distance from the stream sediment site to the MINFILE site was

greater than 1000 m, the stream sediment site mineral deposit model was classed as “unknown.” Some mineral deposit types, listed in Table 1, were not included due to the distance selection criteria.

Mineral deposit models with less than ten MINFILE records were not included. Also, the mineral deposit model (I05 – Polymetallic veins Ag-Pb-Zn ± Au) were not included because the geochemistry of the stream sediment sites associated with I05 overlap with almost every other mineral deposit type. It should be noted that the geochemistry of the mineral deposit models using stream sediment geochemistry is not unique and that compositional overlap is a problem when using geochemistry alone. The resulting deposit models used in the process prediction/validation part of the study are highlighted in bold in Table 1.

patterns and relationships of the variables (PCA only) and the observations. Geospatial rendering, via kriging of the transformed variables (e.g., PC1, t-SNE1) yielded maps for the identification of patterns. Geospatially coherent patterns were considered to represent geochemical processes related to bedrock, alteration, mineralization, weathering, and mass transport.

The application of principal component analysis yielded eigenvalues/eigenvectors that showed significant “structure” in the data. Figure 4 shows a screeplot and a table for the first ten eigenvalues, cumulative eigenvalues, and cumulative percentage eigenvalues. The first four eigenvalues represent most of the variability (56.9%) of the data, while the lesser values may represent under-sampled or random processes.

Figure 5 shows a principal component biplot PC1-PC2 with the observations coded by the attributes of geological terrane, bedrock lithologies, and mineral deposit model assignment at each stream sediment site. Mean values for each of the attributes are shown by the larger symbols on separate biplots, which indicate the compositional difference of the attributes across the PC1-PC2 space.

Computational Geoscience, Table 1 Frequency of MINFILE mineral deposit models in the study area

Mineral deposit model	Description	Frequency
C01	Surficial placers	118
D03	Volcanic redbed Cu	115
E05	Mississippi Valley-type Pb-Zn	2
E12	Mississippi Valley-type Pb-Zn	12

Models highlighted in bold were used in the classification/prediction

Figure 6 shows a scatterplot matrix of the nine independent components (ICA), coded by the attributes of lithology. There is a clear distinction between granitic and metamorphic lithologies throughout the scatterplots. The volcanic and clastic rock types are transitional between the two igneous/metamorphic lithologies.

Figure 7a, b show t-SNE coordinates 3 and nine coded by the attributes of underlying bedrock lithology, mineral

deposit model assignment at each stream sediment site. Mean values for each bedrock lithology and mineral deposit model are shown as larger symbols across the t-SNE3–t-SNE9 space.

The use of the stream sediment geochemistry PCA, ICA, and t-SNE coordinates and the MINFILE mineral deposit model attributes form the basis of process discovery from which the multielement associations and zones of geospatial coherence form a training set (provisional model) from which mineral deposit models can be predicted based.

AOV

An analysis of variance (AOV) was carried out on the PCA space using the tagged mineral deposit models to each stream sediment site. One hundred stream sediment sites with mineral deposit models tagged as “unknown” were included in the analysis. Figure 8 shows a plot of ordered F-values for each principal component. Components with high F-values are better at discriminating between the different mineral deposit types based on 41 PCs. PCs 1, 3, 8, and 13 are the dominant components for mineral deposit discrimination. In the case of the 9-dimensional t-SNE coordinates, t-SNE9, t-SNE3, t-SNE5, and t-SNE4 accounted for most of the variability of the data for the geochemistry tagged with a mineral deposit model. An AOV for the ICA coordinate space indicates that ICA2, ICA5, and ICA9 account for most of the mineral deposit class separation.

Geospatial Coherence in Process Discovery

Figure 9a, b show kriged images for principal components 1 and 3. The stream sediment sampling sites are shown on the images. The choice of these components for geospatial rendering is based on the analysis of variance of the principal components and the discrimination of the mineral deposit models assigned to the geochemical data. The kriged images of PC1 and PC3 show broad geospatially coherent regions that represent associations of elements and sampling sites as shown in the biplot of Fig. 5. Negative PC1 scores represent granitic/felsic rock types and positive scores indicate mafic and sedimentary rock types. Figure 10a, b show kriged images for t-SNE coordinates 3 and 7. The choice of displaying these maps is based on the application of random forests for the prediction of mineral deposit types.

Figure 11a, b show kriged ICA coordinates 2 and 5 that shows broad regional patterns that reflect underlying lithologies across the area. These two variables were determined the most significant for discriminating between the mineral deposit classes.

The kriged images of selected coordinates of the three different metrics show zones of geospatial continuity

Quest South Stream Sediment Geochemistry

Computational Geoscience, Fig. 4 Screeplot of eigenvalues derived from a principal component analysis of logcentered transformed geochemical data. The chart below lists the eigenvalues, percent contribution of the variance, and the cumulative contribution of the variance for each

indicating that these variables represent geospatially coherent processes, which will be tested using methods of classification and prediction.

Process Validation

An initial step in process validation requires an investigation on the ability of the training set of stream sediment geochemistry sites using PCA, t-SNE, and ICA metrics, tagged with a mineral deposit model, to predict the mineral deposit type for stream sediment sites where the mineral deposit model is tagged as unknown. Part of the strategy for use of the metrics is to choose principal components, t-SNE, and ICA coordinates that account for most of the observed signals in PCA biplots and geospatial maps of the spaces. This approach increases the signal-to-noise ratio, which increases the ability to predict mineral deposit types. Stream sediment sites tagged

with a mineral deposit model formed the training set, plus the additional 100 sites tagged as “unknown,” were assigned to the training set.

As described above, there are several methods to classify and predict processes. Three examples are shown here: linear discriminant analysis (LDA), quadratic discriminant analysis (QDA), and random forests (RF). Because geochemical processes can be linear, nonlinear, or a combination of both, it is useful to classify and predict processes with more than one method. This approach provides a measure of the variability of the data and identifies processes that are variable dependent on the method used and an indirect measure of uncertainty.

Table 2 and Fig. 12 show the prediction accuracies for each of the three metrics and three classification methods based on the training sets as described above. The table and figures

Computational Geoscience, Fig. 5 Three PCA biplots of PC1.v. PC2. (a) Scores coded by geological terrane. Mean values for geological terranes are shown by the terrane label placement in the biplot. (b) Scores coded by rock type. Mean values of the different rock types are shown by

the label placement in the biplot. (c) Scores coded by MINFILE mineral deposit model. Mean values for each of the mineral deposits models are shown by the label placement in the biplot

show that some of the mineral deposit models have higher prediction accuracies than others. The mineral deposit models C01 (placer gold), I01 (Au quartz veins), L03 (alkalic porphyry Cu-Au), L04 (porphyry Cu), and L05 (porphyry Mo) have the highest prediction accuracies for all three metrics. Quadratic discriminant analysis (Fig. 12b) and random forests (Fig. 12c) have higher prediction accuracies than those based

on predictions using linear discriminant analysis (Fig. 12a). Figure 12d shows the overall prediction accuracies for the three metrics and three methods. The figure shows that the method of random forests provides the highest level of prediction accuracy. Quadratic discriminant analysis outperforms linear discriminant analysis with the exception of the ICA metric.

Computational Geoscience, Fig. 6 Scatterplot matrix of the ICA coordinates coded by rock type. Legend is the same as Fig. 5b

Figure 13a–f show kriged images of the posterior probabilities generated for mineral deposit predictions using random forests on the three metrics. Each map shows the MINFILE occurrences, coded as yellow crosses, designated for the mineral deposit models C01 (placer Au) and L04

(porphyry Cu-Au). Each stream sediment site that was predicted as C01 (Fig. 13a, c, e) and L04 (Fig. 13b, d, f) are shown as red dots. The kriged images reflect prediction values that range between 0 and 1. The geospatial coherence of the images and the strength of the kriged prediction surfaces

Computational Geoscience, Fig. 7 (a) Scatterplot of t-SNE3.v.t-SNE5 coded by rock type. (b) Scatterplot of t-SNE3.v.t-SNE5 coded by mineral deposit model

Computational Geoscience, Fig. 8 Plot of F-values obtained from an analysis of variance for the mineral deposit models based on the principal components

indicate that the use of the t-SNE metric results in a prediction that is better than that of the ICA or PCA metric. Similarly, the classification for individual stream sediment sites show that fewer sites are predicted for the PCA metric, while the t-SNE

metric shows a much larger number of sites predicted for both the C01 and L04 deposit models. The increased number of predicted sites and the kriged probability surfaces for both models is partly supported by the addition of the known

Computational Geoscience, Fig. 9 (a) Kriged image of principal component 1. Broad regional domains indicating geospatial coherence are evident. The eastern part of the map shows dominantly positive PC1

scores. The central part of the map shows mainly negative PC1 scores. (b) Kriged image of PC3 showing regions of geospatial coherence

MINFILE occurrences shown in yellow crosses. The areas of increased probability and/or sampling sites predicted as C01 or L04, but with few or no MINFILE occurrences may represent regions of previously unrecognized sites with increased mineral deposit potential, or they reflect compositional overlap between deposit types and the site may be mineralized but belong to a different mineral deposit class.

Within the current scope and context of this study, some fundamental assumptions have been made as detailed in Grunsky and Arne (2020).

The geochemical composition of the stream sediment associated with individual mineral deposit models is uniquely distinct. In some cases, this assumption is not warranted. As described above, the mineral deposit model I05 (polymetallic veins) has characteristics that overlap with many other mineral deposit types, which resulted in a significant amount of confusion when applying process prediction. As a result, mineral deposit models with a significant amount of overlap with other models should be removed.

Not all mineral deposit types can be best represented with stream sediment geochemistry. The size fraction and the analytical methods used may not extract unique information to distinguish a sub-cropping mineral deposit or distinguish between different mineral deposit types, as in the case for the polymetallic vein class (I05). The method of dissolution using aqua regia is useful for sheet silicates and sulfide minerals, but aqua-regia digestion does not dissolve many other forms of silicates. Thus, some unique geochemical aspects of specific mineral deposit types based on silicate mineral assemblages may not be recognized.

The MINFILE model identification is accurate. This may not be the case for some types of mineral systems and, as a result, there will be an increase in confusion of prediction. The identification of the mineral deposit profiles, as specified in the MINFILE field “Deposit Type,” may be incorrect or inconclusive, or the locations may be inaccurate. This can lead to misclassification errors in the subsequent application of machine-learning prediction methods.

Computational Geoscience, Fig. 12 Charts that show the predictive accuracy of each mineral deposit type based on linear discriminant analysis (a), quadratic discriminant analysis (b), and random forests (c). Figure (d) shows the overall accuracy of each prediction method and metric

The location of a MINFILE site and the associated stream sediment site may not be within the same catchment area. In the example presented here, the assumption was made that the effect of catchment is not significant. If there is a requirement for the location of a MINFILE site and associated stream sediment site to be in the same catchment, the number of sites for the training set would be significantly reduced.

The fact that the corresponding MINFILE site and the stream sediment sample site are not colocated means that there is always the likelihood that the stream sediment composition does not reflect the observed mineralization at the MINFILE site. The distance threshold of 3.0 km appears to work for some mineral deposit types, but not necessarily for others. Changing the threshold distance for different mineral deposit models may help in a more refined estimate of mineral resource prediction.

Summary

In the realm of computational geosciences, the integration and use of geoscience data as variables (e.g., geochemistry) and attributes (e.g., geology, mineral deposit occurrences) can be studied to identify/discover processes. In geochemical data, processes are recognized through the application of multivariate methods using different metrics (three in the example shown here) that demonstrate element associations related to mineralogy and patterns of geospatial coherence that are related to primary lithology and other processes including metamorphism, weathering, mass wasting, hydrothermal alteration, and base – precious-metal mineralization. These patterns, once identified as processes, can be used as training sets to validate and predict these processes using other data.

Computer-Aided or Computer-Assisted Instruction

Madhurima Panja and Uttam Kumar

Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

“Computer-aided or computer-assisted instruction” (CAI) refers to instruction or remediation presented on a computer, i.e., it is an interactive technique whereby a computer is used to present the instructional material and monitor the learning that takes place. The computer has many purposes in the classroom, and it can be utilized to help a student in all areas of the curriculum. CAI refers to the use of the computer as a tool to facilitate and improve learning. Many educational computer programs are available online (through cloud services) and from computer stores and textbook companies; these tools enhance instructional qualities in several ways. Computer programs are interactive and enhance the learning process by utilizing a combination of text, graphics, vivid animation, sound, and demonstrations. Unlike a teacher-led program, computers offer a different range of activities and allow the students to progress at their own pace. Students are also provided the option of working either individually or in a group. A computer can train the student on the same topic rigorously until they master it. They also provide a facility for immediate feedback so that the students do not continue to practice the wrong skills. Computers capture the students’ attention and engage the students’ spirit of competitiveness to increase their scores.

Introduction

The earliest CAI, Pressey’s multiple-choice machine (Benjamin 1988), was invented in 1925. The main purpose of this machine was to present instructions, test the user, provide feedback to the user based on their responses, and record each attempt as data. Since then, several attempts have been made by researchers to improve Pressey’s multiple-choice machine and use it in various applications.

Computer-assisted or computer-aided instruction (CAI) has been a term of increasing significance during the last few decades and can also be referred to as computer-based instruction (CBI), computer-aided or computer-assisted learning (CAL). In general, CAI can be described as the set of instructions provided by a computer program that enhance the learning experience of users. However, the keyword for

understanding the CAI is *interaction*. Computers can facilitate interaction during the learning process in several ways, e.g., the user might interact with the learning material that has been programmed systematically. Alternatively, there might be interaction between user and the tutor, even the computer might host peer interaction or interaction between members of whole “virtual” learning communities. The concept of user interaction with content was initially introduced in the 1980s, and it forms the primary reason behind the rapid success of CAI. During the last few decades, the explosion of technological advancements allowed reliable and inexpensive communication that facilitated interaction between humans via computer programs, and massive open online course (MOOC) is a popular example of CAI.

Types of CAI Programs

Several types of software, viz., drill and practice, tutorial, simulations, problem-solving, gaming, and discovery are used for providing the course content in a CAI program (Blok et al. 2002). A brief description of these software is provided next:

- In drill-and-practice programs, the student rehearses different elements of teaching and develops related skills. This program is highly user-friendly and is one of the most prevalent types of computer software for many years. This type of software relies heavily on positive reinforcement, i.e., a reward follows a correct response. For example, if a drill and practice program was designed to help users to learn multiplication tables, then the drill might be presented with a car race game and the refueling of the car would depend on the correct answer provided by the student on the multiplication question. Drill-and-practice software deals primarily with lower-order thinking skills and also have a tracking facility that records the progress of the user. Moreover, this software does not utilize the full power of a computer and hence it can be used continuously to provide students with practice sessions and evaluate them.
- The use of “computers as tutors” is as widespread as that of drill-and-practice programs. The tutorial programs are specifically designed to teach certain concepts or skills and then assess the student’s understanding of such concepts by providing them the opportunity to practice. This type of program tries to act like a simulating teacher. The tutorial sessions are usually very interactive and involve explanations, questions, feedback, as well as correctives. Students are also provided with computerized tutorials that can be accessed multiple times until they become adept in those concepts.

- A simulation is a representation of real-world event, object or phenomenon. Simulation attracts the students' attention by setting up reality in classroom where the learners can see the results of their action. This feature of CAI provides great advantages for the science curriculum. With the help of simulation, experiments that are difficult, time-consuming, and costly could be realized in the classroom. Simulations also help in mathematics by producing visualizations of three-dimensional objects, which is not possible otherwise. This is a very powerful application of computers, and the educational community has the potential to capitalize on this type of software. Simulation software are now supported by artificial intelligence, and virtual and augmented reality.
- Problem-solving is a type of CAI program that allows the user to manipulate the variables, and feedback is provided based on these manipulations. The major difference between a problem-solving software and a simulation software is that the former does not necessarily utilize realistic scenarios like the latter one.
- Gaming-based CAI program is the most stimulating use of computers. These programs are a kind of simulation that offer competitive games from academic and nonacademic background to its users. The games are based upon various themes, e.g., some games might encourage their users to win individually, or some might give opportunity to the users to work as a team and explore the environment with other team members. However, irrespective of the theme based on which the game is designed, the primary objective behind these games is to produce valuable learning environment.
- Discovery is another approach used in a CAI program to engage its users for skill development. In this approach, the users are provided with a large database of information regarding a specific content area and are asked to analyze, compare, and evaluate their findings based on explorations of the database.

Features of CAI

CAIs have served the purpose of enhancing students' learning by affecting cognitive processes and increasing motivation. There are certain factors by which computer programs can facilitate this learning experience.

- Personalized information – CAI captures learner's interest in a given task by providing them with personalized information. For example, if a CAI program is allotted the task of explaining the concept of big data to the users, then it will use several animated objects to demonstrate the concepts and thereby increase learning by decreasing the

cognitive load on the learner's memory. This will allow the student to perform search and recognition processes and make more informational relationships (Fig. 1).

- Trial sessions – CAI encourages its learners to practice challenging problems. These practice sessions are intrinsically motivating and also carry other significant advantages such as personal satisfaction, challenge, relevance, and promotion of a positive perspective on a lifelong journey.

Types of Student Interactions in CAI

1. Recognition – In recognition type of interactions, the students are only required to identify whether or not a particular study material or question presented by a machine has been demonstrated previously.
2. Recall – This type of interaction requires the student to do more than just recognizing the information previously presented. The students are expected to reproduce the information precisely in a similar manner as was done previously by the machine.
3. Reconstruction – The reconstruction type of interaction does not engage the learners superficially like that of recognition and recall. In this type of interaction, the learners are required to reproduce concepts or principles that have been previously learnt. A basic difference between recall and reconstruction is that the latter does not show any relevant information except the question to the users when they are constructing the answers.
4. Intuitive understanding – The most difficult type of interaction between a CAI program and a student is intuitive understanding. These interactions often involve prolonged activity and are directed at “getting a feel” for an idea, developing sophisticated pattern-recognition skills, or developing a sense of strategy. Here, subject matter understanding must be demonstrated through experimental analysis and will be judged accordingly by experts. In this interaction, it is not possible to evaluate the students' performance by some explicit criteria stored in the computer. The activities that are used for assessing the intuitive understanding of learners include discovering principles behind simulations, problem-solving using classical techniques, and developing a feel for diagnostic strategies.
5. Constructive understanding – Unlike the other interactions mentioned above, constructive understanding is extremely open-ended and encourages the students to “create” knowledge. The learners are usually provided with an “open” enquiry and are expected to do genuine research instead of just providing solutions to questions on the content that is already known. From the users' point of view, she/he will be going beyond her/his knowledge and

Computer-Aided or Computer-Assisted Instruction,

Fig. 1 Demonstration of a learner using a CAI program © [Sujit Kumar Chakrabarti.]

may be testing her/his own hypothesis, developing new theory, and drawing conclusions based on her/his own work.

How Is CAI Implemented?

Teachers are primarily responsible to review the computer programs or games or online activities before they are introduced to the students. The mentors should understand the context of the lessons in any CAI program and then determine their usefulness. The CAI program must satisfy some basic requirements. Firstly, the program should be able to supplement the lesson and give basic skills to the learners. Secondly, the content should be presented in such a manner that the student will remain interested in the topic. However, it must be ensured that the students don't waste a substantial amount of time with too much animation in a content. Finally, the program must be at the correct level for the class or the individual students, and should neither be too simple nor too complex. Once these requirements are fulfilled, the teachers might allow the students to operate these computer programs to enhance their learning experience.

Advantages of CAI

There are several advantages of using a CAI program as listed below:

1. CAI programs are self-pacing; they allow the students to learn at their own pace, totally unaffected by the performance of others. Owing to its self-directed learning nature, the learners have the freedom to choose when, where, and what to learn. It is also very useful for slow learners.
2. Information is presented in a structured manner in CAI software, which is useful when there exists a hierarchy of facts and rules on the subject.
3. CAI requires active participation from its users, which is not necessarily true while reading a book or attending a lecture.
4. The immediate feedback mechanism of CAI software provides a clear picture to the student about their progress. Learners can identify the subject areas in which they have improved and in which they need to improve further.
5. While teaching a concept, the CAI programs enable students to experiment with different options and explore the results after any manipulations, thereby reducing the time taken to comprehend difficult concepts.

Computer-Aided or Computer-Assisted Instruction, Fig. 2 Three-dimensional surface generation in GRASS GIS with a simulation tool

6. CAI offers a wide range of experience that is otherwise not available to the student. It enables the students to understand concepts clearly using various techniques such as animation, blinking, and graphical displays. CAI software acts as multimedia that helps to understand difficult concepts through a multisensory approach.
7. CAI provides individual attention to each and every student. Additionally, a lot of practice sessions are also given to the students that can prove useful, especially for low-aptitude ones.
8. CAI programs are great motivators and encourage the students to take part in challenging activities, thus, enhancing their reasoning and decision-making abilities.

Limitations of CAI

Apart from the abovementioned advantages, there are certain restrictions of CAI software as described next:

1. Although CAI programs allow experimentation through simulation, the hands-on experience is missing. These programs cannot develop manual skills like handling apparatus in a chemical experiment, working with machines in a physical laboratory, workshop experience, etc.
2. There are real costs associated with the development of CAI systems. They require dedicated time from

programmers to design such a software as well as sophisticated infrastructure for deployment.

3. The course content of any CAI program needs to be updated frequently, otherwise, it will become obsolete.
4. Since the objective and method of teaching decided by a teacher may be different from that of a CAI program designer, the program might fail to fulfill the expectation of the teacher.
5. Teachers might be reluctant about using a computer in teaching and may be unwilling to spend extra time on the preparation, selection, and use of CAI packages. It may be perceived as a threat to their job.
6. The overuse of multimedia in CAI software may divert the attention of the student from the course.
7. CAI packages depend upon the configuration of the hardware; previously built packages might become completely useless after major hardware upgradation.

Application of CAI in Geospatial Analysis

In geospatial science, CAI programs are very useful in the simulation of real-world scenarios. There are many free and open-source software that provide such simulation and visualization capabilities. Geographic Resources Analysis Support System (GRASS) GIS (<https://grass.osgeo.org/>) is a software built for vector and raster geospatial data

management, geoprocessing, spatial modeling, and visualization released under the GNU General Public License. It has programs to render three-dimensional views from contours at a given spatial location that allow users to generate interpolated surface of the terrain and simulate the environment. Figure 2a shows contours and Fig. 2b, c shows interpolated raster (digital elevation model) of a small region from a larger terrain shown in Fig. 2d. Three-dimensional surface generation in GRASS GIS with a simulation tool is shown in Fig. 2e. The dataset used to generate the figures are from the North Carolina sample open data available for GRASS GIS users (<https://grass.osgeo.org/download/data/>).

These types of simulations can be realized in a classroom environment without actually visiting the spatial point of interest. A fly-through can be generated and stored in the form of popular video formats for multimedia display.

Conclusion

This chapter was a brief overview of the features and usage of CAI. Nowadays, with the rapid technological development, it is almost impossible to keep away from electronic devices like laptops and smartphones. However, with the help of CAI software, students can be motivated to use electronic devices for their greater good. CAI provides the learners with the freedom to experiment with different options and get instant feedback. Another crucial feature of CAI is its one-to-one interaction, which not only provides individual attention to the students but also allows them to learn at their own pace. This assistance from technology provides opportunities to the teachers to work with students who need more of their time. It is also a proven concept that the animations that a CAI package offers enable the students to learn difficult concepts quite easily and are useful in virtual laboratories. With all these great features that CAI has to offer to its users, it is always recommended to use this technology under proper supervision, otherwise, the learning becomes too mechanical. If all these factors are taken into consideration, one might appropriately declare that CAI has the potential to transform the educational system of our society (Bayraktar 2001).

Concentration-Area Plot

Behnam Sadeghi

EarthByte Group, School of Geosciences, University of Sydney, Sydney, NSW, Australia

Earth and Sustainability Science Research Centre, University of New South Wales, Sydney, NSW, Australia

Definition

Element contour maps are representative tools to discriminate the anomalous areas from background areas using optimum thresholds. Such thresholds could be defined via the target element concentration-area (C-A) log-log plot. Such an idea was developed as the C-A fractal model, by Cheng et al. (1994), which is the first fractal/multifractal model applied in geochemical anomaly classification.

Introduction

Classification models, represented as classified maps, are the main tools to discriminate anomalous areas of mineralization from background areas. To expose the subtle patterns (e.g., geochemical patterns) associated with various mineralization and lithologies, a variety of mathematical and statistical models have been developed and applied to the available data. Traditional statistical methods, advanced geostatistical models and simulations, fractal/multifractal models, machine learning, deep learning, and artificial intelligence are some of the models that have been developed (Sadeghi 2020). Fractal geometry was proposed by Mandelbrot (1983); later, in 1992, it was taken into further consideration in geosciences by Bölviken et al. – see the ► “Fractal Geometry in Geosciences” and ► “Singularity Analysis” entries for further details. Then, Cheng et al. (1994) developed the first geochemical anomaly classification fractal model, called concentration-area (C-A). The C-A model is simply based on the relation between the target element concentration and the area confined by the relevant concentration contours (Cheng et al. 1994; Zuo and

Wang 2016; Sadeghi 2020, 2021; Sadeghi and Cohen 2021). In this entry, the C-A fractal model and its log-log plot will be studied in detail. After that, several other fractal models, particularly concentration-volume (C-V) (Afzal et al. 2011) and concentration-concentration (C-C) (Sadeghi 2021) fractal models, which were developed based on the C-A model, will be discussed.

Methodology: Concentration-Area Fractal Model

The C-A fractal model, as one of the important fractal models, describes the spatial distribution of geochemical data based on the spatial relationship of geochemical concentrations to the occupied areas (Cheng et al. 1994):

$$A(\rho \leq v) \propto \rho^{-a_1}; A(\rho > v) \propto \rho^{-a_2}$$

where $A(\rho)$ denotes the area occupied by concentrations greater than a concentration contour value ρ ; v represents a threshold concentration contour; and a_1 and a_2 are characteristic exponents. The thresholds defined by the C-A fractal model are cross-points of lines fitted, by Least Squares (LS) method, through log-log plots of A versus ρ .

One question that may come to mind is about the relation between the fractal geometry, log-log plots, e.g., log-log plots of A versus ρ , fitting straight lines and calculating their slopes (fractal dimensions). Such slopes represent the exponents of the power-law relation in the C-A model equation (Zuo and Wang 2016). The answer, in summary, is that if we implement the logarithm (e.g., log 10) on both sides of the C-A fractal model equation, the result will be the equation of a straight line as below:

$$Y = mX + C$$

where X and Y are the axis coordinates of the points generating the lines, m denotes the slope of the lines, and C is a constant.

Therefore, analysts need to fit straight lines to the fractal log-log plots to find their cross-points as the desired thresholds. The main method implemented to do so is the LS fitting method (Carranza 2009), as will continue to be discussed.

The LS method, proposed by Carl Friedrich Gauss (1795) (Stigler 1981; Bretscher 1995), is a regression analysis to do linear and nonlinear regression. It minimizes the sum of the difference between the actual values and the fitted values predicted by a model, which are the squared residuals (r^2).

The data pairs are (x_i, y_i) that $i = 1, \dots, n$, where x_i is an independent variable and y_i is a dependent variable. If the model function is $f(x, \beta)$, the i th residual would be calculated as given below (cf. Stigler 1981; Bretscher 1995; Strutz 2011):

$$r_i = y_i - f(x_i, \beta) = y_i - \sum_{j=1}^n X_{ij} \beta_j$$

So the sum of the squared residuals is:

$$S = \sum_{i=1}^n r_i^2$$

If β_0 is the y intercept, and β_1 is the slope of the straight line, the model function is given by:

$$f(x, \beta) = \beta_0 + \beta_1 x$$

If the sum of the squared residuals, S , is minimum, the LS method would be optimum. So, in order to have the $S_{\min}$, its gradient should be set to 0, meaning:

$$\frac{\partial S}{\partial \beta_j} = 2 \sum_{i=1}^m r_i \frac{\partial r_i}{\partial \beta_j} = 0, (j = 1, \dots, n)$$

Then, the derivatives are:

$$\frac{\partial r_i}{\partial \beta_j} = -X_{ij}$$

so,

$$\frac{\partial S}{\partial \beta_j} = 2 \sum_{i=1}^m \left(y_i - \sum_{k=1}^n X_{ik} \beta_k \right) (-X_{ij}), (j = 1, \dots, n)$$

If $\hat{\beta}$ minimizes S , we will have:

$$2 \sum_{i=1}^m \left(y_i - \sum_{k=1}^n X_{ik} \hat{\beta}_k \right) (-X_{ij}), (j = 1, \dots, n)$$

and now, the normal equations are obtained:

$$\sum_{i=1}^m \sum_{k=1}^n X_{ij} X_{ik} \hat{\beta}_k = \sum_{i=1}^m X_{ij} y_i, (j = 1, 2, \dots, n)$$

The matrix notation of this equation is:

$$(X^T X) \hat{\beta} = X^T y$$

where X^T is the matrix transpose of X .

Another significant parameter in the straight-line fitting using the LS technique that should be taken into account is the determination coefficient (R^2), which is the square of the correlation coefficient (R) between predicted values and actual values; so, the range of R^2 is between 0 and 1. It is considered as a key output of regression analysis. In other words, it is the proportion of the variance in the dependent variable, which is predictable from the independent variable. The reason why the coefficient is important is because a linear

relation is supposed to be strong/weak if the points on a scatterplot are close to/far from the straight line. Therefore, scientifically, instead of simply saying there is a strong or weak relationship between the variables, analysts must apply a measure of how strong/weak the association is.

If $R^2 = 0$, it means that the dependent variable cannot be predicted from the independent variable; if $R^2 = 1$, it explains the dependent variable can be predicted from the independent variable, without error; and if R^2 is between 0 and 1, it denotes the extent to which the dependent variable is predictable. For instance, if $R^2 = 0.10$, it means that 10% of the variance in Y is predictable from X .

The formula of R considering R^2 for a linear regression model with one independent variable is (Caers 2011):

$$R = \frac{1}{n-1} \sum_{i=1}^n \left(\frac{x_i - \bar{x}}{s_x} \right) \cdot \left(\frac{y_i - \bar{y}}{s_y} \right)$$

where n is the number of samples or points on the scatter plot; x_i and y_i are the x and y values of the i th sample, $\bar{x}$ and $\bar{y}$ are the

mean of the x and y values; and s_x and s_y are the standard deviations of x and y .

Case Study: Sweden

Sadeghi and Cohen (2019) applied the C-A model to Swedish till geochemical data, collected by Geological Survey of Sweden (Andersson et al. 2014) (Fig. 1). The thresholds obtained were applied to generate the classified volcanic massive sulfide (VMS) Cu geochemical anomaly map (Fig. 2). Main anomalies are concentrated in Caledonides and Northern Norrbotten metallogenic provinces.

Summary of the Other Models Developed Based on the C-A Fractal Model

Several other models have been developed based on the C-A model such as the 3D format of C-A, called concentration-

Concentration-Area Plot, Fig. 1 Swedish till sample locations, and the IDW interpolated map of Cu. (From Sadeghi 2020; Sadeghi and Cohen 2021)

Concentration-Area Plot, Fig. 2 VMS Cu geochemical anomalies recognized by C-A fractal modeling of till data in Sweden. (From Sadeghi and Cohen 2019)

Concentration-Area Plot,

Fig. 3 (a) Highly, (b) moderately, and (c) weakly mineralized zones, in addition to (d) wall rocks, and (e) the cross-section of the mineralized zones, characterized by C-V fractal model. (From Sadeghi et al. 2012)

volume (C-V) (Afzal et al. 2011), spectrum-area (S-A) (Cheng et al. 2000), and its 3D format, called power spectrum-volume (P-V) (Afzal et al. 2012), and concentration-concentration (C-C) (Sadeghi 2021) fractal models. For S-A and P-V fractal models see the ► “Spectrum-Area Method” entry. Here C-V and C-C fractal models are introduced.

The C-V fractal model was developed by Afzal et al. (2011) to define different mineralization zones in 3D:

$$V(\rho \leq v) \propto \rho^{-a_1}; V(\rho > v) \propto \rho^{-a_2}$$

where $V(\rho)$ denotes the volume occupied by concentrations greater than ρ .

In Fig. 3, Sadeghi et al. (2012) have applied the C-V model to the Fe data of Zaghia iron ore deposit, Central Iran, to characterize different mineralized zones.

Sadeghi (2020, 2021) proposed the C-C fractal model as a bivariate modification of the C-A model (Fig. 4):

Concentration-Area Plot, Fig. 4 The C-C model applied to Cyprus soil data to classify Cu and In geochemical anomalies based on each other. (From Sadeghi 2021)

$$C_2 (\geq C_1) = FC_1^{-D}$$

where C_1 is the target element concentration, $C_2(\geq C_1)$ is the cumulative concentration of the element, which is highly correlated with the target element, with concentration values

higher than or equal to C_1 ; F is a constant and D is the fractal dimension. Unlike the C-A model, in the C-C model the element C_2 is not measured in the area, i.e., it is measured in a subspace containing subareas in which C_1 values exceed a certain value.

Summary and Conclusions

Fractal/multifractal models provide robust tools to characterize mineralization zones and discriminate geochemical anomalies from the background using the obtained thresholds. The C-A fractal model is the first fractal model, which has been efficiently applied to geochemical anomaly classifications. It works based on the relation between element concentrations and their occupied contour areas. It has been applied to various geological studies, then modified to several other models such as C-V in 3D, S-A and its 3D format, P-V, and recently C-C fractal models.

Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

Constrained optimization is defined as the process of optimizing an objective function with respect to some variables on which constraints are defined. In general, for optimization, the objective function is either minimized in case of a cost or energy function or maximized in case of a reward or utility function. The constraints defined on the variables can be hard constraints which put a hard limit on the value of the variable or it can be a soft constraint having some penalized values of the variables in the objective function if the condition on the variables is not satisfied.

Introduction

Optimization problem can be easily seen in most of the real world economic decisions which are generally subject to one or more constraint(s). Some real world examples of the economic decisions are:

1. When buying goods or services, consumers make decisions on what to buy, constrained by the fact that it must be affordable and under their budget.
2. Industries often make decisions on maximizing their profit subject to having limited production capacity, limited

costing, and also maintaining high quality of goods or services that are above standards.

Basic Nomenclature

A set $S \subset R^n$ is called:

- Affine if $x, y \in S$ implies $\theta x + (1 - \theta)y \in S$ for all $\theta \in R$.
- Convex if $x, y \in S$ implies $\theta x + (1 - \theta)y \in S$ for all $\theta \in [0, 1]$.
- Convex cone if $x, y \in S$ implies $\lambda x + \mu y \in S$ for all $\lambda, \mu \geq 0$.

A function $f: R^n \rightarrow R$ is called

- Affine if $f(\theta x + (1 - \theta)y) = \theta f(x) + (1 - \theta)f(y)$ for all $\theta \in R$ and $x, y \in R^n$.
- Convex if $f(\theta x + (1 - \theta)y) \leq \theta f(x) + (1 - \theta)f(y)$ for all $\theta \in [0, 1]$ and $x, y \in R^n$.

General form: A constrained optimization problem has the following general form:

$$\min f(x)$$

such that

$$g_i(x) = c_i; \quad \text{for } i = 1, \dots, n; c \in \mathfrak{R} \text{ Equality constraint}$$

$$h_j(x) \geq d_j; \quad \text{for } j = 1, \dots, m; d \in \mathfrak{R} \text{ Inequality constraint}$$

Here, $f(x)$ is the objective function that needs to be optimized in terms of minimization such that g_i and h_j (hard constraints) are satisfied.

Convexity: This problem is called a convex problem if the objective function f is convex, the inequality constraints $h_j(x)$ are convex, and the equality constraints $g_i(x)$ are affine. Convex analysis is the study of properties of convex functions and convex sets with applications in convex minimization.

Solution methods: To solve the constrained optimization problem, several methods have been proposed. Some of these methods are described below:

- (i) **Substitution method:** For simple objective functions having two or three variables with equality constraints, this method is favorable as the solution. Here, a composite function is made by substituting the value of the equality constraint in the objective function as shown below:

$$\begin{aligned} \text{Let } \min f(x) &= x \cdot y \\ \text{such that } y &= x - 11 \end{aligned}$$

Hence, substituting y in $f(x)$ we get:

$$\begin{aligned} f(x) &= x(x - 11) \\ f(x) &= x^2 - 11x \end{aligned}$$

According to first-order necessary condition, $\frac{\partial f}{\partial x} = 0$. Therefore,

$$\begin{aligned} \frac{\partial f}{\partial x} &= 2x - 11 \\ 2x - 11 &= 0 \\ x &= 5.5 \end{aligned}$$

- (ii) **Lagrange multiplier:** This method is used to minimize or maximize the objective function subject to one or more equality constraints only. To solve the objective function, a Lagrangian function is defined which is a relation between the gradient of the objective function and the gradients of the equality constraints, which lead to the reformulation of the original problem. The Lagrange multiplier theorem for the objective function $f(x)$ and equality constraint $g(x)$ is stated as below:

$$L(x, \lambda) = f(x) + \lambda g(x)$$

Here, $\lambda \in \mathfrak{R}$ is the unique Lagrange multipliers such that $\partial f(x) = \lambda^T \partial g(x)$.

First order condition: A differentiable function f of one variable defined on an interval $F = [ae]$. If an interior-point $\hat{x}$ is a local/global minimizer, then $f'(\hat{x}) = 0$; if the left-end-point $\hat{x} = a$ is a local minimizer, then $f(a) \geq 0$; if the right-end-point $\hat{x} = e$ is a local minimizer, then $f(e) \leq 0$. First-order necessary condition (FONC) summarizes the three cases by a unified set of optimality/complementarity slackness conditions: $a \leq x \leq e$, $f'(x) = y^a + y^e$, $y^a \geq 0$, $y^e \leq 0$, $y^a(x - a) = 0$, $y^e(x - e) = 0$. Note: If $f(x) = 0$, then it is also necessary that $f(x)$ is locally convex at $\hat{x}$ for being a local minimizer.

Second order condition: Second-order condition states that if first-order condition satisfies and if $f(\hat{x}) \geq 0$, or the function f is strictly locally convex, then $\hat{x}$ is a local minimizer.

Duality: Consider the Lagrange multiplier theorem for objective function $f(x)$ and equality constraint $g(x)$ where $L(x, \lambda) = f(x) + \lambda g(x)$ and there is a Lagrange dual function $D(\lambda) = \inf_{x \in \mathfrak{R}^n} L(x, \lambda)$. λ and v are dual feasible if $\lambda \geq 0$ and $D(\lambda)$ is finite. The dual function D is always concave. Weak duality holds when $D(\lambda) \leq f(x)$.

- (iii) **Karush–Kuhn–Tucker (KKT) conditions:** Constrained optimization with objective function having

both inequality and equality constraints can be solved as a more generalized method (as compared to the Lagrange method) called the Karush–Kuhn–Tucker or the KKT conditions. Similar to Lagrange method, the KKT condition method solves the constrained optimization problem using the Lagrange function $L(x, \lambda)$ whose optimal point is the saddle point.

Some of the other popular optimization algorithms like gradient descent, simulated annealing, local search algorithm are based on approximation methods in order to find a local or global minimum to optimize the objective function. As one of the most popular optimization algorithms, the gradient descent is a first-order iterative optimization algorithm for finding a local minimum of a differentiable objective function. The idea is to take repeated steps in the opposite direction of the gradient of the function at the current point, because this is the direction of steepest descent. In order to use gradient descent algorithm in the presence of constraints, projected gradient descent algorithm was proposed where the constraint is imposed on the feasible set of the parameters.

Constrained Optimization Application in Geospatial Science

Now, let us see one geospatial application of constrained optimization in land cover (LC) classification. Most land cover features occur at finer spatial scales compared to the resolution of primary remote sensing satellites. Therefore, observed data are a mixture of spectral signatures of two or more LC features resulting in mixed pixels (see Fig. 1); the mixed pixel problem has been commonly observed in hyperspectral remote sensing data. In other words, the observed data are mixture of spectral signatures of the individual objects present in mixed pixels, which could be due to two

Constrained Optimization, Fig. 1 A mixed pixel comprised of three land cover types

reasons: (1) the spatial resolution of the sensor is not high enough to separate different objects, these can jointly occupy a single pixel, and the resulting spectral measurement is a composite of the individual spectra, (2) mixed pixels may also result when distinct objects are combined into homogeneous (intimate) mixtures (Plaza et al. 2004).

One of the solutions to the mixed pixel problem is the use of spectral unmixing techniques such as linear mixture model (LMM) or linear unmixing to disintegrate pixel spectrum into its constituent spectra. Here, the observation vector in the low spatial resolution imagery is modeled as a linear combination of the endmembers, and given the endmembers present in the scene, the fractional abundances are extracted through the ordinary least squares error approaches. In most cases, the fractional abundances are constrained to be positive and sum to one (Heinz and Chang 2001). LMM infers a set of pure object's spectral signatures (called endmembers) and fractions of these endmembers (abundances) in each pixel of the image, that is, the objects are present with relative concentrations weighted by their corresponding abundances. The endmembers can be either derived using endmember extraction algorithms, from the image pixels, or obtained from an endmember spectral library available a priori. In LMM, the observation vector $\mathbf{y}$ for each pixel is related to endmember signature $\mathbf{E}$ by a linear model as

$$\mathbf{y} = \mathbf{E}\boldsymbol{\alpha} + \boldsymbol{\eta} \quad (1)$$

where each pixel is a M -dimensional vector $\mathbf{y}$ whose components are the digital numbers corresponding to the M spectral bands. $\mathbf{E} = [e_1, \dots, e_{n-1}, e_n, e_{n+1}, \dots, e_N]$ is a $M \times N$ matrix, where N is the number of classes, $\{e_n\}$ is a column vector representing the spectral signature of the n th target material, and $\boldsymbol{\eta}$ accounts for the measurement noise. For a given pixel, the abundance of the n th target material present in the pixel is denoted by α_n , and these values are the components of the N -dimensional abundance vector $\boldsymbol{\alpha}$. Further, components of the noise vector $\boldsymbol{\eta}$ are zero-mean random variables that are independent and identically distributed (i.i.d.). Therefore, covariance matrix of the noise vector is $\sigma^2 \mathbf{I}$, where σ^2 is the variance and $\mathbf{I}$ is $M \times M$ identity matrix.

LMM renders an optimal solution that is in unconstrained or partially constrained or fully constrained form. A partially constrained model imposes either the abundance non-negativity constraint (ANC) or abundance sum-to-one constraint (ASC) while a fully constrained model imposes both. ANC restricts the abundance values from being negative and ASC confines the sum of abundances of all the classes to unity. The conventional approach to extract the abundance values is to minimize $\|\mathbf{y} - \mathbf{E}\boldsymbol{\alpha}\|$ as in (2):

$$\boldsymbol{\alpha}_{\text{UCLS}} = (\mathbf{E}^T \mathbf{E})^{-1} \mathbf{E}^T \mathbf{y} \quad (2)$$

which is termed as unconstrained least squares (UCLS) estimate of the abundance. UCLS with full additivity is a nonstatistical, nonparametric algorithm that optimizes a squared-error criterion but does not enforce the non-negativity and unity conditions.

To avoid deviation of the estimated abundance fractions, ANC given in (3) and ASC given in (4) are imposed on the model in fully constrained least squares (FCLS):

$$\alpha_n \geq 0 \forall n : 1 \leq n \leq N \quad (3)$$

$$\sum_{n=1}^N \alpha_n = 1 \quad (4)$$

ANC and ASC constrain the value of abundance in any given pixel between 0 and 1. When only ASC is imposed on the solution, the sum-to-one constrained least squares (SCLS) estimate of the abundance is

$$\alpha_{\text{SCLS}} = \mathbf{E}^T \mathbf{E}^{-1} \left(\mathbf{E}^T \mathbf{y} - \frac{\lambda}{2} \mathbf{1} \right), \quad (5)$$

where

$$\lambda = \frac{2 \left(\mathbf{1}^T (\mathbf{E}^T \mathbf{E})^{-1} \mathbf{E}^T \mathbf{y} - 1 \right)}{\mathbf{1}^T (\mathbf{E}^T \mathbf{E})^{-1} \mathbf{1}}. \quad (6)$$

The SCLS solution may have negative abundance values, but they add to unity. FCLS (Chang 2003; Heinz and Chang 2001) extends non-negative least squares (NNLS) algorithm (Lawson and Hanson 1995) to minimize $\|\mathbf{E}\alpha - \mathbf{y}\|$ subject to $\alpha \geq 0$ by including ASC in the signature matrix $\mathbf{E}$ by a new signature matrix (**SME**) defined by

$$\mathbf{SME} = \begin{bmatrix} \theta \mathbf{E} \\ \mathbf{1}^T \end{bmatrix} \quad (7)$$

with

$$\mathbf{1} = (11111 \dots N \text{ times})^T \text{ and } \mathbf{s} = \begin{bmatrix} \theta \mathbf{y} \\ \mathbf{1} \end{bmatrix} \quad (8)$$

θ in (7) and (8) regulates ASC. Using these two equations, the FCLS algorithm is directly obtained from NNLS by replacing signature matrix $\mathbf{E}$ with **SME** and pixel vector $\mathbf{y}$ with $\mathbf{s}$. ANC is a major difficulty in solving constrained linear unmixing problems as it forbids the use of Lagrange multiplier. One solution is the replacement of $\alpha_n \geq 0 \forall n : 1 \leq n \leq N$ with absolute ASC (AASC), $\sum_{n=1}^N |\alpha_n| = 1$ (Chang 2003).

AASC allows usage of Lagrange multiplier along with exclusion of negative abundance values. This leads to optimal constrained least squares solution satisfying both ASC and AASC, known as Modified FCLS (MFCLS). MFCLS utilizes SCLS solution and the algorithm terminates with all nonnegative components (Kumar et al. 2017).

Case Study

Problem: Solve the below constraint optimization problem by applying KKT conditions for the objective function $f(x, y)$ subject to the constraint function $h_1(y)$ and $h_2(y)$.

$$\min f(x, y) = (x - 2)^2 + 2(y - 1)^2$$

subject to:

$$h_1(x, y) \Rightarrow x + 4y \leq 3 \quad (\text{A})$$

$$h_2(x, y) \Rightarrow -x + y \leq 0 \quad (\text{B})$$

Solution: Applying generalized Lagrangian function:

$$L(x, y, \lambda_1, \lambda_2) = f(x, y) + \lambda_1 h_1(x, y) + \lambda_2 h_2(x, y)$$

$$L(x, y, \lambda_1, \lambda_2) = (x - 2)^2 + 2(y - 1)^2 + \lambda_1 (x + 4y - 3) + \lambda_2 (-x + y)$$

with $\lambda_1 \geq 0$ and $\lambda_2 \geq 0$. Calculating the partial derivatives to find the optimal point as below:

$$\frac{\partial L}{\partial x} = 2(x - 2) + \lambda_1 - \lambda_2 = 0 \quad (9)$$

$$\frac{\partial L}{\partial y} = 4(y - 1) + 4\lambda_1 + \lambda_2 = 0 \quad (10)$$

$$\lambda_1 (x + 4y - 3) = 0 \quad (11)$$

$$\lambda_2 (-x + y) = 0 \quad (12)$$

$$x + 4y \leq 3 \quad (13)$$

$$-x + y \leq 0 \quad (14)$$

$$\lambda_1 \geq 0 \quad (15)$$

$$\lambda_2 \geq 0 \quad (16)$$

We need to check four possible cases as shown below:

Case I: When $\lambda_1 = 0$ and $\lambda_2 = 0$.

Using Eqs. 1 and 2, we have $x = 2$ and $y = 1$; these values of x and y do not satisfy Eqs. 5 and 6. So this is not a possible or optimal solution.

Case II: When primal constraint A is inactive and primal constraint B is active, that is, $\lambda_1 = 0$, and $-x + y = 0$.

then substituting the above values in Eqs. 1 and 2 gives:

$$2(x - 2) - \lambda_2 = 0$$

and

$$4(y - 1) + \lambda_2 = 0.$$

By solving above two equations, we have:

$$x = \frac{4}{3}, y = \frac{4}{3}, \lambda_2 = -\frac{4}{3}$$

The values of λ_2 does not satisfy Eqs. 7 and 8. So, this is not a possible or optimal solution.

Case III: When primal constraint A is active and primal constraint B is inactive, that is, $x + 4y = 3$ and $\lambda_2 = 0$ then substituting the above values in Eqs. 1 and 2 gives:

$$2(x - 2) + \lambda_1 = 0$$

and

$$4(y - 1) + 4\lambda_1 = 0.$$

By solving the above two equations, we have:

$$x = \frac{5}{3}, y = \frac{1}{3}, \lambda_1 = \frac{2}{3}$$

The values of x, y, λ_1 , and λ_2 satisfy all Eqs. 1–8. So, this case is one of the possible or optimal solution.

Case IV: When both primal constraint A and B are active, that is, $x + 4y = 3$ and $-x + y = 0$.

then by solving above two equations we have:

$$x = \frac{3}{5}, y = \frac{3}{5}.$$

Substituting the above values in Eqs. 1 and 2:

$$\lambda_1 = \frac{22}{25}, \lambda_2 = -\frac{48}{25}$$

The values of λ_2 do not satisfy Eq. 8. So this is not a

possible or optimal solution. Hence, the only possible solution to the objective function f is case III. Therefore,

$$\text{Optimal solution : } x = \frac{5}{3}, y = -\frac{1}{3}$$

$$\text{Optimal value : } f^*(x, y) = \left(\frac{5}{3} - 2\right)^2 + 2\left(\frac{1}{3} - 1\right)^2$$

$$\text{Optimal value : } f^*(x, y) = 1$$

Summary and Conclusions

In this chapter, we saw some basic method of solutions for solving constrained optimization problem. Solution methods such as substitution method, Lagrange multipliers, and KKT conditions were discussed in detail with respective case studies at the end of the chapter. Furthermore, the global optimality conditions can be checked by KKT conditions and the dual problem provides a lower-bound and an optimality gap.

Convex Analysis

Indu Solomon and Uttam Kumar

Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

Convex analysis is a subfield of mathematical optimization, the word meaning of “optimal” is “best” and optimization techniques strive to bring out the best solution. Convex analysis studies the properties of convex functions and convex sets and aims to minimize convex functions over convex sets. It has application in various fields such as automatic control systems, signal processing, deep learning, data analysis and model building, finance, statistics, economics, and so on.

Introduction

In the beginning of 1960s, the works of mathematicians Ralph Tyrrell Rockafellar and Jean Jacques Moreau brought about great advancement in the field of convex analysis. An example for optimization in the field of economics could be profit maximization or cost minimization. As the system complexity increases, analytical solutions become infeasible, and we can reach the optimal solution only through convex analysis and optimization. The goal of convex analysis is to determine x^* , such that $f(x^*) \leq f(x)$ (Au 2007) for all other points of x . Loss functions used in machine learning techniques are convex in nature, and hence, best model parameters are estimated through optimization techniques like gradient decent. Linear programming is a special case of convex optimization where the objective function is linear and the constraints consist of linear equalities and inequalities.

An optimization problem can be defined as finding x that satisfies the following objective function

$$\begin{aligned} & \text{minimize} && f_0(x) \\ & \text{subject to} && f_i(x) \leq 0, \quad i = 1, \dots, m \\ & && g_j(x) = 0, \quad j = 1, \dots, p \end{aligned} \quad (1)$$

where $f_0: \mathcal{R}^n \rightarrow \mathcal{R}$ is the objective function to be optimized and $x \in \mathcal{R}^n$ is the n -dimensional variable, $f_i(x)$ are inequality constraints, and $g_j(x)$ are equality constraints of the objective function. A valid solution exists if the optimization variable x is a feasible point and x has to satisfy m inequality constraints, $f_i: \mathcal{R}^n \rightarrow \mathcal{R}$ and p equality constraints $g_i: \mathcal{R}^n \rightarrow \mathcal{R}$. A convex optimization problem is the one which satisfies an

extra requirement, that is, all functions $\{f_0, \dots, f_m\}$ are convex functions and $\{g_1, \dots, g_p\}$ are affine functions.

Affine Functions

A function $f: \mathcal{R}^n \rightarrow \mathcal{R}^m$ is affine, if it is a sum of linear function and a constant. It has a form $f(x) = Ax + b$, where $A \in \mathcal{R}^{m \times n}$ and $b \in \mathcal{R}^m$.

Affine Sets

A set $C \subseteq \mathcal{R}^n$ is an affine set if a line connecting any two points in C lies in C . If any $x_1, x_2 \in C$ and $\theta \in \mathcal{R}$, $\theta x_1 + (1 - \theta)x_2 \in C$ (Boyd et al. 2004). Therefore, the set C must contain all linear combination of points in C , provided the coefficients θ_i in the linear combination sum to one. Examples are line, plane, and hyperplane.

Convex Sets

Any set C is convex if the line segment between any two points in C lies in C . For any $x_1, x_2 \in C$ and any θ in $0 \leq \theta \leq 1$, the combination is given by

$$\theta x_1 + (1 - \theta)x_2 \in C. \quad (2)$$

Every affine set is also convex. A convex combination of points in C is the weighted average of points with θ_i as weight for the point x_i . Examples of convex and non-convex sets are shown in Fig. 1.

Convex Analysis, Fig. 1 Convex sets and nonconvex sets

Convex Functions

A function $f: \mathcal{R}^n \rightarrow \mathcal{R}$ is convex, if $\text{dom}f$ is a convex set, and if for all $x, y \in \text{dom}f$ and $\theta, 0 \leq \theta \leq 1$ given by

$$f(\theta x + (1-\theta)y) \leq \theta f(x) + (1-\theta)f(y) \quad (3)$$

where $\text{dom}f$ is the domain of function f and is the subset of points of $x \in \mathcal{R}^n$ for which function f is defined (Boyd et al. 2004). The criteria in Eq. (3) are geometrically explained in Fig. 2. It means that the function f lies below the line segment connecting any two points on the function.

First-Order Conditions

If the function f is differentiable and ∇f exists at each point in $\text{dom}f$, then f is convex if and only if $\text{dom}f$ is convex and

$$f(y) \geq f(x) + \nabla f(x)^T (y-x) \quad (4)$$

for all $x, y \in \text{dom}f$. Figure 3 is the geometrical representation of the inequality described in Eq. (4) and it states that a convex function always lies above its tangent. Hence, the tangent to a convex function is its global underestimator and if we have the local information about a function, we can derive the global information.

Convex Analysis, Fig. 2 Convex function criteria

Convex Analysis, Fig. 3 First-order condition

Second-Order Conditions

Suppose if f is twice differentiable and its Hessian or second derivative exists at each point in $\text{dom}f$, then the function f is convex iff its $\text{dom}f$ is convex and its second derivative or hessian is positive semi-definite for all $x \in \text{dom}f$.

$$\nabla^2 f(x) \geq 0 \quad (5)$$

The condition $\nabla^2 f(x) \geq 0$ can be geometrically interpreted as the function $f(x)$ must have positive curvature. The gradient ∇ of $f(x)$ with $x \in \mathcal{R}^n$ is given by

$$\nabla f = \begin{bmatrix} \frac{\partial f}{\partial x_1} \\ \frac{\partial f}{\partial x_2} \\ \vdots \\ \frac{\partial f}{\partial x_n} \end{bmatrix}. \quad (6)$$

The hessian ∇^2 for $f(x)$ with $x \in \mathcal{R}^n$ is given by,

$$\nabla^2 f = \begin{bmatrix} \frac{\partial^2 f}{\partial x_1^2} & \frac{\partial^2 f}{\partial x_1 \partial x_2} & \cdots & \frac{\partial^2 f}{\partial x_1 \partial x_n} \\ \frac{\partial^2 f}{\partial x_2 \partial x_1} & \frac{\partial^2 f}{\partial x_2^2} & \cdots & \frac{\partial^2 f}{\partial x_2 \partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial^2 f}{\partial x_n \partial x_1} & \frac{\partial^2 f}{\partial x_n \partial x_2} & \cdots & \frac{\partial^2 f}{\partial x_n^2} \end{bmatrix} \quad (7)$$

Example-1: $f = x^2 + xy + y^2$

$$\nabla f = \begin{bmatrix} 2x + y \\ x + 2y \end{bmatrix}$$

$$\nabla^2 f = \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}$$

Eigen values of $\nabla^2 f$ is $\lambda = 1, 3$ and the eigen values are > 0 . Hence, $\nabla^2 f$ is positive semi-definite and the second-order conditions of convexity are satisfied (Fletcher 2013). Figure 4 shows the 3D plot of $f = x^2 + xy + y^2$.

Example-2: $f = x^2 + 3xy + y^2$

$$\nabla f = \begin{bmatrix} 2x + 3y \\ 3x + 2y \end{bmatrix}$$

$$\nabla^2 f = \begin{bmatrix} 2 & 3 \\ 3 & 2 \end{bmatrix}$$

Eigen values of $\nabla^2 f$ are $\lambda = 5, -1$, and all the eigen values are not ≥ 0 . Hence, $\nabla^2 f$ is not positive semi-definite and the

Convex Analysis, Fig. 4 3D plot of the Convex function $f = x^2 + xy + y^2$

second-order conditions of convexity are not satisfied. Figure 5 shows the 3D plot of $f = x^2 + 3xy + y^2$.

Convex Analysis, Fig. 5 3D plot of the concave function $f = x^2 + 3xy + y^2$

Operations that preserve Convexity

Non-negative Weighted Sums

If f is a convex function and $\alpha \geq 0$, then αf is a convex function.

Sum

If f_1 and f_2 are convex functions, then their sum $f_1 + f_2$ is also convex. A non-negative weighted sum of convex functions is convex.

Point-wise maximum

If $\{f_1, f_2, \dots, f_n\}$ are convex functions, then $f = \max \{f_1, f_2, \dots, f_n\}$ is convex.

Duality

The Lagrangian

Consider the optimization problem defined in Eq. (1). Lagrangian duality is used to modify the objective function by including the constraints. The updated objective function

is a weighted sum of the constraints with the existing objective function. Lagrangian L is defined as $L : \mathcal{R}^n \times \mathcal{R}^m \times \mathcal{R}^p \rightarrow \mathcal{R}$.

$$L(x, \lambda, v) = f_0(x) + \sum_{i=1}^m \lambda_i f_i(x) + \sum_{i=1}^p v_i h_i(x) \quad (8)$$

In Eq. (8), λ_i is the Lagrange multiplier associated with the i^{th} inequality constraint $f_i(x) \leq 0$ and v_i is the Lagrange multiplier associated with the i^{th} equality constraint $h_i(x) = 0$.

The Lagrange Dual Function

Lagrange dual function $g : \mathcal{R}^m \times \mathcal{R}^p \rightarrow \mathcal{R}$ is the minimum value of the Lagrangian over x : for $\lambda \in \mathcal{R}^m, v \in \mathcal{R}^p$ given by

$$\begin{aligned} g(\lambda, v) &= \inf_{x \in \mathcal{D}} L(x, \lambda, v) \\ &= \inf_{x \in \mathcal{D}} \left(f_0(x) + \sum_{i=1}^m \lambda_i f_i(x) + \sum_{i=1}^p v_i h_i(x) \right) \end{aligned} \quad (9)$$

The dual function is a pointwise infimum of a family of affine functions, and hence, it is concave. The dual function gives the lower bound of the optimal value p^* for any $\lambda \geq 0$ and any v , $g(\lambda, v) \leq p^*$. Let $\hat{x}$ be a feasible point, then $f_i(\hat{x}) \leq 0$ and $h_i(\hat{x}) = 0$ and $\lambda_i \geq 0$. Mathematically,

$$\sum_{i=1}^m \lambda_i f_i(\hat{x}) + \sum_{i=1}^p v_i h_i(\hat{x}) \leq 0 \quad (10)$$

Then Eq. (9) becomes

$$\begin{aligned} L(x, \lambda, v) &= \left(f_0(\hat{x}) + \sum_{i=1}^m \lambda_i f_i(\hat{x}) + \sum_{i=1}^p v_i h_i(\hat{x}) \right) \\ &\leq f_0(\hat{x}) \end{aligned} \quad (11)$$

Therefore,

$$g(\lambda, v) = \inf_{x \in \mathcal{D}} L(x, \lambda, v) \leq L(x, \lambda, v) \leq f_0(\hat{x}) \quad (12)$$

Every feasible point satisfies $g(\lambda, v) \leq f_0(\hat{x})$ and hence for every feasible point, $g(\lambda, v) \leq p^*$. For a nontrivial lower bound p^* , $\lambda \geq 0$ and $\lambda, v \in \text{dom } g$.

Example – Least Squares Solution

Minimize $x^T x$ subject to $Ax = b$. The problem has equality constraints and the Lagrangian is given by, $L(x, v) = x^T x + v(Ax - b)$ in the domain $R^n \times R^p$. The dual function is given by $g(v) = \inf_x L(x, v)$. The optimality condition is given by

$$\nabla_x L(x, v) = 2x + A^T v = 0 \quad (13)$$

which gives $x = -\frac{1}{2}A^T v$. Hence, the dual function can be written as $g(v) = -\frac{1}{4}v^T A A^T v - b^T v$ and the dual function is a concave quadratic function with domain R^p . The lower bound property of dual function for any $v \in R^p$ gives

$$-\frac{1}{4}v^T A A^T v - b^T v \leq \inf \{x^T x | Ax = b\} \quad (14)$$

Examples of Optimization Techniques in Geospatial Applications

Spatial data analysis and linear programming can be combined to obtain an optimal solution to optimal location problems. An optimal geographical location for a desired building of a restaurant/mall/park/anything of interest can be found by setting the mathematical model with the right optimization criteria (Guerra and Lewis 2002). Convex optimization technique was used for hyperspectral image visualization (Cui et al. 2009). Maintaining the spectral distances, spectral discrimination and interactive visualization were three objectives of hyperspectral image visualization techniques. A combination of principal component analysis and linear programming techniques was used for mapping the spectral

signature of pixels to RGB colors. Cat swarm optimization technique was used for feature extraction from satellite images (Prabhakaran et al. 2018). Cat optimized algorithm distinguishes the inner, outer, and extended boundary along with the land cover. Examples of convex analysis in geospatial applications are terrain analysis (Prabhakaran et al. 2018), landslide susceptibility mapping (Pham et al. 2019), and in interactive hyperspectral visualization (Cui et al. 2009).

Summary and Conclusions

In this chapter, we have explored mathematical optimization and especially convex optimization. Optimization concepts like affine sets, convex sets, and convex functions were explained. The first-order and second-order optimality conditions for a convex function put a constraint on the function that the hessian of the function must be positive semi-definite for the function to be convex. Duality concept combines the function and the constraints into a single equation with the help of the Lagrange multiplier. Optimization concepts are useful in geospatial applications and a few examples were mentioned in this chapter.

Copula in Earth Sciences

Sandra De Iaco and Donato Posa

Department of Economics, Section of Mathematics and Statistics, University of Salento, Lecce, Italy

Synonyms

Multivariate distribution; Spatial dependence

Definition

A **copula** is a multivariate distribution, defined on the unit hypercube, which is characterized by uniform marginals. In particular, it describes the dependence of **multivariate distributions** by marginal distributions. By recalling the result of Sklar (1959), any multivariate distribution $F(z_1, z_2, \dots, z_n)$ can be written as a copula of its one-dimensional marginal distribution $F_i(z)$, $i = 1, 2, \dots, n$, that is

$$F(z_1, \dots, z_n) = C(F_1(z_1), F_2(z_2), \dots, F_n(z_n)). \quad (1)$$

Moreover, the function C in (1) is unique, if the **marginal distributions** are assumed to be continuous.

Introduction

Quality parameters in Earth Sciences are characterized by significant spatial variability. In Geostatistics the evaluation of this variability is based on the use of the variogram. In addition, copulas provide a valid chance to give information on the dependence structures for multivariate distributions and in particular bi-dimensional copulas can be an alternative to the use of the traditional measures of spatial correlation (i.e., variograms and covariance functions) in describing the spatial variability.

Thus, the copula-based models are widely utilized in stochastic interpolation (alternatively to kriging) or for simulation.

Measures of Spatial Variability

Traditionally, the **spatial variability** of various variables encountered in Earth Sciences are analyzed by using geostatistical methods (Matheron 1971). For geostatistical studies, spatial observations, for a given variable Z of interest, are assumed to be a finite realization of a random function (or random field), which is usually supposed to satisfy the

hypothesis of second-order stationarity or at least the hypothesis of intrinsic stationarity. Under these conditions, the covariance function or the variogram of Z at two different locations $\mathbf{x}_1$ and $\mathbf{x}_2$ of the spatial domain, depends on the spatial separating vector $\mathbf{h} = \mathbf{x}_1 - \mathbf{x}_2$ and can be estimated from the available sample data. Thus, the spatial variability or spatial correlation is well described by these moments, however they cannot highlight potential differences in the spatial dependence related to extreme values or to central values, since they represent the spatial correlation obtained as an integral over the whole distribution of the variable values. Regarding this aspect, it is well known that different quantiles can be characterized by a different spatial dependence structure (Journel and Alabert 1989). For example, extreme values can have a spatial dependence structure which is different from the one related to central values.

Indicator variograms represent a way to assess the difference in dependence with respect to the values of the variable under study. For this reason, the indicator approach used in simulation and interpolation studies requires that variogram models are fitted for each selected threshold. However, an indicator variogram model is fitted for each threshold separately and it is not applied any stochastic model. Therefore the results might be not consistent; the monotonicity of the estimated indicator variogram (corresponding to the estimated distribution function) for the various cutoff values might not be guaranteed. With the support of the indicator variograms, Journel and Alabert (1989) pointed out that the dependence between variables often deviates significantly from the **Gaussian**. Another advantage in using indicator variogram emerges when data have skewed distributions, as usually happened in Earth Sciences applications. In these cases, the estimation of the variogram (which is based on the squared differences between the values measured at different locations) might be severely influenced by few anomalous squares. These problems can be mitigated by adopting the indicator approach, with the effort of computing several indicator variograms. In alternative, another technique to be used to face the same problem is to consider the ranks for interpolation, as illustrated in Journel and Deutsch (1996).

In the following, the concept of copulas and its help in the study of the spatial variability of earth quality variables is underlined. In particular, it is clarified that the dependence structure between random variables can be represented through copulas with no information on the marginal distributions. In other terms, copulas is interpreted as the key measure of the dependence over the range of quantiles.

Some Fields of Application

Nowadays, an emerging interest in applying copulas in the spatial context is noticeable. There are numerous applications

of copulas in finance, where it is important to study the dependence between extremes (Embrechts et al. 2002) and to adopt appropriate non-Gaussian type of dependence for the estimation of financial risks. The non-Gaussian structure of dependence can also be found in other contexts, such as in hydrology, for groundwater modeling (Gomez and Wen 1998), where the consequences of the departure from normality on some aspects regarding ground water flow and transport were analyzed. Copulas were also applied on stochastic rainfall simulation or on extreme value statistics, among other by De Michele and Salvadori (2003); Favre et al. (2004).

Basic Concepts

As already specified, copulas are multivariate distributions defined on the unit hypercube with uniform marginals. In particular, for $n = 2$ the definition of bivariate copula (or bi-dimensional copula) C can be given as follows:

$$C : [0, 1]^2 \rightarrow [0, 1] \quad (2)$$

and has to fulfill the following properties:

- I $C(u, 0) = C(0, u) = 0$ and $C(1, u) = C(u, 1) = u$,
- II given $u_1 \geq v_1$ and $u_2 \geq v_2$, then $C(u_1, u_2) + C(v_1, v_2) - C(u_1, v_2) - C(v_1, u_2) \geq 0$.

These last property guarantees the non-negativity of the probability associated to any rectangle in the unit square. For a n -dimensional space, the multivariate copula is a function

$$C : [0, 1]^n \rightarrow [0, 1] \quad (3)$$

which is characterized by uniform marginals,

$$C(\mathbf{u}^{(i)}) = u_i, \quad \text{if } \mathbf{u}^{(i)} = (1, \dots, 1, u_i, 1, \dots, 1),$$

and is zero if at least one of the arguments is zero, that is

$$C(\mathbf{u}) = 0, \quad \text{if } \mathbf{u} = (u_1, \dots, u_i, \dots, u_n), \\ \exists i : u_i = 0.$$

For every n -dimensional hypercube in the domain $[0, 1]^n$ (called unit hypercube), that is for $[\mathbf{u}', \mathbf{v}'] \subseteq [0, 1]^n$, the associated probability has to be nonnegative:

$$V_C([\mathbf{u}', \mathbf{v}']) \geq 0,$$

where $V_C([\mathbf{u}', \mathbf{v}']) = \Delta_{u'_n}^{v'_n} \Delta_{u'_{n-1}}^{v'_{n-1}} \dots \Delta_{u'_1}^{v'_1} C(\mathbf{u})$ is the n -difference of C on $[\mathbf{u}', \mathbf{v}']$ and a first-order difference is defined as $\Delta_{u'_k}^{v'_k} C(\mathbf{u}) = C(u_1, \dots, u_{k-1}, v'_k, u_{k+1}, \dots, u_n) - C(u_1, \dots, u_{k-1}, u'_k, u_{k+1}, \dots, u_n)$.

The readers may refer to Joe (1997) or Nelsen (1999) for more information.

Some Features of Copulas

If C is assumed to be an absolutely continuous function, the corresponding copula density, denoted with $c(\cdot)$, is expressed as

$$c(u_1, \dots, u_n) = \frac{\partial^n C(u_1, \dots, u_n)}{\partial u_1 \dots \partial u_n}. \quad (4)$$

In addition, it is worth introducing the conditional copula can which be written as

$$C(u_1 | U_2 = u_2, \dots, U_n = u_n) = \frac{1}{c(u_2, \dots, u_n)} \cdot \frac{\partial^{n-1} C(u_1, \dots, u_n)}{\partial u_2 \dots \partial u_n} \quad (5)$$

Thus, a copula C can be viewed as a multivariate cumulative distribution function, while a copula density c is interpreted as the strength of dependence. Given two independent variables, then the bivariate copula of their joint distribution function is obtained through the product of the marginals $C[F(z_1), F(z_2)] = F(z_1)F(z_2)$; for this reason, it is known as the product copula and the density copula is equal to 1. In the case of full dependence, the copula becomes $C[F(z_1), F(z_2)] = \min[F(z_1), F(z_2)]$.

The invariance of the copula of a multivariate distribution with respect to monotonic transformations of the marginal variables represents one of the main advantages. Thus, some common data transformations (a normal score transformation and Box-Cox transformations, included logarithms) do not affect the copula. On the basis of this characteristic, the use of copula is preferred to the approaches based on covariance functions or variograms, as these last are strongly influenced by the marginal distributions. Another relevant property of a copula is associated to the possibility of pointing out whether the corresponding dependence is related to the intensity of the variable realizations, in other term, whether high (low) values present a strong (weak) spatial dependence.

A bi-dimensional copula highlights a symmetrical dependence if

$$C(u_1, u_2) = C(1 - u_1, 1 - u_2) - 1 + u_1 + u_2, \quad (6)$$

or in terms of its density

$$c(u_1, u_2) = c(1 - u_1, 1 - u_2). \quad (7)$$

Note that the symmetric property is given with respect to the axis $u_2 = 1 - u_1$ of the unit square.

Copula Families

Building new families of copulas is not an easy task. Traditional copula families include the Archimedean class (Genest and MacKay 1986) as well as the Farlie-Gumbel-Morgenstern class (Nelsen 1999). Moreover, the Gaussian copulas is another well-known family of copulas which is used to explain the dependence form of the multivariate normal distribution. They are frequently used in hydrology, although the term copula is not popular; they are applied for regressions, or in case of normal score transformation. In Table 1, some well-known families of bivariate copula are given together with their parameter space and the dependence structure.

Note that the normal copula class presents a symmetric density, which can be properly expressed as follows:

$$c(u_1, \dots, u_n) = k_n \exp\left(0.5 \mathbf{z}^T (\boldsymbol{\Sigma}^{-1} - \mathbf{I}) \mathbf{z}\right) \quad (8)$$

where $u_i = \Phi(z_i)$, Φ is the standardized normal distribution function, k_n is a normalizing constant, $\boldsymbol{\Sigma}$ is the correlation matrix, and $\mathbf{I}$ is called identity matrix.

For $n = 2$, $\boldsymbol{\Sigma}$ depends on the only parameter ρ , which is the correlation coefficient between the two variables. A graphical representation of the bivariate Gaussian copula together with the associated copula density given $\rho = 0.85$ is shown in Fig. 1. Note that the symmetry of the density, as specified in (7). It is also worth highlighting that, for the user, the dependence can be better visualized through the density rather than the copula itself.

Similarly to the Gaussian family, several other bivariate copula classes have multivariate extensions, which are desirable in spatial modeling. However, these families are considered not flexible enough, since they depend only on one or two parameters. Moreover, it might happen that the multivariate distribution has different pairwise dependence structures across its margins, as a consequence a single family might not be able to capture this behavior. These restrictions can be get through with vine copulas, as will be clarified in one of the next sections. The introduction of a bivariate spatial copula into a vine copula for interpolation has been described by Gräler and Pebesma (2011) and is extended in Gräler (2014), where convex combinations of bivariate copulas parametrized by distance are combined in a vine copula (also known as pair-copula construction).

Copulas for Describing Spatial Variability

In spatial statistics, copulas characterize the joint multivariate distribution associated to the regionalized variables at different locations of the domain of interest. In this context, the variable at each location of the domain is assumed to have the same probability distribution.

Let $Z = \{Z(\mathbf{x}), \mathbf{x} \in D\}$ be a random function, where D represents the spatial domain (one-, two-, or three-

Copula in Earth Sciences, Table 1 Some well-known families of copulas

Name	Copula	Parameter	Dependence structure
Gaussian	$C_N(u_1, u_2; \rho) = \Phi(\Phi^{-1}(u_1), \Phi^{-1}(u_2))$	ρ	Tail independence: $\lambda_U = \lambda_L = 0$
Student- t	$C_{ST}(u_1, u_2; \rho, \nu) = T(t_v^{-1}(u_1), t_v^{-1}(u_2))$	ρ, ν	Symmetric tail dependence: $\lambda_U = \lambda_L =$ $2t_{\nu+1}\left(-\sqrt{\nu+1}\sqrt{1-\rho}/\sqrt{1+\rho}\right)$
Gumbel	$C_G(u_1, u_2; \delta) = \exp\{-(\log u_1)^\delta + (\log u_2)^\delta\}^{1/\delta}$	$\delta \geq 1$	Asymmetric tail dependence: $\lambda_U = 2 - 2^{1/\delta}, \lambda_L = 0$
Rotated Gumbel	$C_{RG}(u_1, u_2; \delta) = u_1 + u_2 - 1 + C_G(1 - u_1, 1 - u_2; \delta)$	$\delta \geq 1$	Asymmetric tail dependence: $\lambda_U = 0, \lambda_L = 2 - 2^{1/\delta}$
Plackett	$C_P(u_1, u_2; \theta) = \frac{1}{2(\theta-1)}[1 + (\theta-1)(u_1 + u_2)] +$ $-\sqrt{[1 + (\theta-1)(u_1 + u_2)]^2 - 4\theta(\theta-1)u_1u_2}$	$\theta \geq 0,$ $\theta \neq 1$	Tail independence: $\lambda_U = \lambda_L = 0$
Frank	$C_F(u_1, u_2; \theta) = -\frac{1}{\theta} \log\{1 + [(exp^{-\theta u_1} - 1)(exp^{-\theta u_2} - 1)/exp^{-\theta} - 1]\}$	$0 < \theta < \infty$	Tail independence: $\lambda_U = \lambda_L = 0$
Clayton	$C_{CL}(u_1, u_2; \theta) = \max\{(u_1^{-\theta} + u_2^{-\theta} - 1), 0\}$	$\theta > 0$	Asymmetric tail dependence: $\lambda_U = 2 - 2^{1/\theta}, \lambda_L = 0$

Copula in Earth Sciences, Fig. 1 (a) Gaussian copula characterized by correlation $\rho = 0.85$ and (b) the associated copula density

dimensional space) and $(\mathbf{x})$ a point in the same domain. The available spatial data represent a single finite realization of the random function Z , thus it is not possible to assess the multivariate copulas from them. However, in order to describe the spatial variability, it is interesting to introduce the bivariate marginal copulas, similarly to what is proposed with variograms or covariance functions. For this aim, according to a stationarity hypothesis, the spatial copula C_S of two random variables associated to two locations $\mathbf{x}$ and $\mathbf{x}'$ of the domain is assumed to be dependent on the separating vector $\mathbf{h} = \mathbf{x} - \mathbf{x}'$, rather than the specific locations $\mathbf{x}$ and $\mathbf{x}'$.

For any two selected quantiles u_1, u_2 ,

$$C_S(\mathbf{h}, u_1, u_2) = P\{F_Z[Z(\mathbf{x})] < u_1, F_Z[Z(\mathbf{x} + \mathbf{h})] < u_2\} \\ = C(F_Z[Z(\mathbf{x})], F_Z[Z(\mathbf{x} + \mathbf{h})]), \quad (9)$$

where F_Z denotes the marginal distribution of the variable Z and it is assumed to be independent from the location $\mathbf{x}$. Note that the behavior of any couple of variables at two locations, characterized by a separation vector $\mathbf{h}$, is described by the bivariate distribution function whose dependence is described by the bivariate copula.

Similarly to variogram, copula is not a function of the locations $\mathbf{x}$ and $\mathbf{x}'$, since it depends only on the separation vector $\mathbf{h}$. It is worth to underline that the hypothesis that the random function Z has bivariate marginal copulas which are translation invariant is stronger than the **second-order stationarity (or the intrinsic hypothesis)**.

Differently from the approach of Journel and Deutsch (1996) who used the variogram to describe the dependence, on average, in the rank space, this approach considers copulas to assess the dependence structure with respect to the entire range of quantiles.

It is worth noting that building a multivariate copula, given two-dimensional marginals, is not an easy task. For example, the Gaussian copula represents one of the multivariate copula obtained from its bivariate marginals, given a positive definite matrix (covariance matrix). Since this is not always possible, the construction of an alternative theoretical copula model representing the dependence of regionalized variables is presented just by way of explanation; even in this case, it is shown that the construction of the copula can be obtained from its bivariate marginals. The copulas can be constructed by transforming the variables and using their marginal distribution, similarly to the case of indicator variables.

Indeed, an evident link between copulas and indicator variograms can be provided. In particular, for any threshold z_α , the indicator variogram γ_α can be expressed as follows:

$$\gamma_\alpha(\mathbf{h}) = F_Z^{-1}(\alpha) - C_S[\mathbf{h}, F_Z^{-1}(\alpha), F_Z^{-1}(\alpha)]. \quad (10)$$

The indicator cross-variogram $\gamma_{\alpha_1, \alpha_2}$, for the thresholds α_1, α_2

$$\gamma_{\alpha_1, \alpha_2}(\mathbf{h}) = 0.5 \min[F_Z^{-1}(\alpha_1), F_Z^{-1}(\alpha_2)] \\ - C_S[\mathbf{h}, F_Z^{-1}(\alpha_1), F_Z^{-1}(\alpha_2)]. \quad (11)$$

In other terms, copulas provide the same information given by the direct and cross-indicator variograms; indeed copulas have the advantage to offer a representation with more parsimonious parameterization.

In conclusion, the hypothesis that the bivariate marginals is dependent on the lag vector $\mathbf{h}$ is analogous to the second-order stationarity hypothesis which is considered in

geostatistics, however the former is more general than the latter.

Estimation Aspects

The bivariate copulas estimation from the observations $z(\mathbf{x}_1), \dots, z(\mathbf{x}_n)$ at the samples locations $\mathbf{x}_1, \dots, \mathbf{x}_n$ can be obtained by first computing the sample distribution function $F_n(z)$. On the basis of this sample distribution function and for any given vector $\mathbf{h}$, the set $S(\mathbf{h})$ of those pairs of distribution function values associated to the observations at points with separation vector $\mathbf{h}$, is computed, that is

$$S(\mathbf{h}) = \{ [F_n(z(\mathbf{x}_i)), F_n(z(\mathbf{x}_j))] \mid (\mathbf{x}_i - \mathbf{x}_j) \approx \mathbf{h} \text{ or } (\mathbf{x}_j - \mathbf{x}_i) \approx \mathbf{h} \} \quad (12)$$

Note that $S(\mathbf{h})$ is a set of points in the unit square and is, by definition, symmetric with respect to the major axis $u_1 = u_2$ of the unit square, therefore, it is clear that if $(u_1, u_2) \in S(\mathbf{h})$, then $(u_2, u_1) \in S(\mathbf{h})$. In practice, the set $S(\mathbf{h})$ is defined for various lags $\mathbf{h}$. The sample copula density are easily computed through the sample frequencies $\hat{c}$, for a fixed lag $\mathbf{h}$, as follows:

$$\hat{c}\left(\mathbf{h}, \frac{2i-1}{2k}, \frac{2j-1}{2k}\right) = \frac{k^2}{|S(\mathbf{h})|} |S_{ij}(\mathbf{h})|, \quad i, j = 1, \dots, k, \quad (13)$$

where $|\cdot|$ denotes the cardinality and

$$S_{ij}(\mathbf{h}) = \left\{ (u_1, u_2) \in S(\mathbf{h}) : \frac{i-1}{k} < u_1 \leq \frac{i}{k} \text{ and } \frac{j-1}{k} < u_2 \leq \frac{j}{k} \right\}.$$

Note that if the cardinality set $S(\mathbf{h})$ is sufficiently high, a kernel smoothing can be used to approximate the bivariate density.

Copula Modeling

As done for structural analysis based on variogram, where the sample variogram is fitted to a model which satisfies the conditional negative definiteness condition, even the empirical copulas have to be described through a model. Thus, after the estimation of copulas, which reflect the spatial dependence structure of the observations, the modeling step is necessary.

It is important to highlight that in some cases, the complexity of phenomenon under study requires (for interpolation or simulation) a very high dimension of the dependence structure. Then, the multivariate copula (associated to the

random variables at the locations in the studied domain) should be characterized by bivariate marginals which recall the empirical bivariate copulas.

In modeling the multivariate copula, the properties listed below should be fulfilled:

1. The multivariate marginals should be stable, in the sense that any multivariate marginal copula for a fixed set of locations should not depend on the set of other fixed locations considered to define the multivariate copula.
2. The dependence should be characterized by wide range, with strong dependence for geographically close set of points and weaker and weaker dependence or independence for points at increasing distance.
3. The multivariate copula should be flexible enough that the dependence structure takes into account the geometry of the related set of points.

In literature, there exist various copula models, however not all satisfy the features which are desirable for analyzing the spatial dependence of random functions. The main problem derives from the difficulty to find a joint distribution (or copula) for n ($n > 2$) random variables that optimally honors the bivariate marginals. For this aim, although there are different conditions that ensure the existence of such a copula (Drouet and Kotz 2001), building a multivariate copula (with $n > 2$), on the basis of given bivariate marginals, is not an easy task and sometimes it is not possible at all on for the incompatibility of the bivariate marginals. Rueschendorf (1985) proposed an interesting method for constructing multivariate distributions and it can be used to define copulas (Drouet and Kotz 2001). Bardossy (2006) started from the selection of a multivariate distribution, then a suitable multivariate copula was found. Indeed, a multivariate copula can be defined through a multivariate distribution, then the multivariate model is obtained through a combination with the univariate marginal of the regionalized variable.

On the basis of **Sklar's theorem**, given a multi-dimensional distribution function F , whose margins are absolutely continuous, the Eq. (1) is valid, where C (uniquely determined) is a copula function. A copula function C is determined from the function F by considering

$$C(u_1, u_2, \dots, u_n) = F(F_1^{-1}(u_1), F_2^{-1}(u_2), \dots, F_n^{-1}(u_n)), \quad (14)$$

where F_i , $i = 1, 2, \dots, n$ are the corresponding univariate distribution functions of F . On the other hand, any copula C can be applied to combine a set of univariate distribution functions $F_1, F_2, \dots, F_n$ in order to build a multivariate distribution F . This technique is often adopted, for example, in case of multivariate normal or t copula.

Various well-known multivariate copula functions only depend on a restricted number of parameters which can cause that the dependence would not change with respect to the spatial distance between two points and that the third property above-mentioned would be violated. The multivariate normal copula and the Farlie-Gumbel-Morgenstern copula present $\binom{n}{2}$ parameters. However, the former is symmetric, that is satisfies Eq. (7), the latter has the drawback of showing a decaying correlation between pairs of variables with the increase in the number of points (Drouet and Kotz 2001). This last feature represents a critical aspect especially when the two variables corresponds to very close points $\mathbf{x}_1$ and $\mathbf{x}_2$ and it is expected to have a high correlation. Thus, this multivariate copula does not respect the first two properties of the above list. Copula models can be built on the basis of Eq. (14) starting from a given multivariate distribution. Moreover, interesting constructions of multivariate copulas can be obtained through non-monotonic transformations from the Gaussian copula; indeed, as underlined in Bardossy (2006), they are asymmetric. For example, given a nonmonotonic function $g(t)$ and an n -dimensional normal random variable $Y \sim N(\mathbf{m}, \mathbf{\Gamma})$, whose expected value is $\mathbf{m}^T = (m, \dots, m)$ and covariance matrix $\mathbf{\Gamma}$, then $\mathbf{V}$ is defined for each coordinate $j = 1, \dots, n$ as

$$V_j = g(Y_j). \quad (15)$$

For simplicity, all marginals are assumed to have unit variance. By using (15), the copula of the transformed multivariate distribution is not necessarily Gaussian. For example, the copula of the non-centered multivariate chi-square distribution can be easily obtained by considering the transformation function $g(t) = t^2$ and $V_j = Y_j^2$. In this way, the corresponding n -dimensional distribution has identical one-dimensional marginals. In particular, the marginal variables follows a χ^2 distribution with a degree of freedom equal to 1, under the hypothesis that the expected value is equal to zero ($\mathbf{m} = \mathbf{0}$). Thus, after getting the multivariate density function f_n , the multivariate copula density can be determined through the following equality:

$$f_n(z_1, z_2, \dots, z_n) = c(F_1(z_1), F_2(z_2), \dots, F_n(z_n)) \cdot f_1(z_1) \cdot f_2(z_2) \cdots f_n(z_n), \quad (16)$$

where f_i , $i = 1, 2, \dots, n$ are the marginal density.

The presence of an **asymmetric dependence** can be assessed by comparing the strength of the dependence of high values and the one related to low values. In particular, the following ratio of the joint probability between high values (exceeding the quantile $1 - u$) and the joint probability between low values (not exceeding a quantile u):

$$A(u) = \frac{2u - 1 + C(1 - u, 1 - u)}{C(u, u)} \quad (17)$$

is such that $A(u) > 1$ if high values present a stronger dependence than the low values, while $A(u) < 1$ if high values present a weaker dependence than the low values; the case $A(u) \approx 1$ occurs when the dependence is the same. Moreover, as highlighted in Joe (1997), the tail dependence for a given copula offers information about multivariate extreme value distributions, that is about the dependence in the upper and lower quadrants. However, the tail dependence is rarely applied in spatial statistics, since the main focus does not often regard the extremes, but the location where the observations that are greater than certain thresholds are recorded.

For the spatial context, the elements of the correlation matrix $\mathbf{\Gamma}$ are the correlation function $\rho(\mathbf{h})$, where $\mathbf{h} = \mathbf{x}_i - \mathbf{x}_j$, $i = 1, 2, \dots, n$. Thus, for any set of points $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$, the generic element of the covariance matrix associated to the Gaussian variable $\mathbf{Y}$, from which the copula is generated, is $\mathbf{\Gamma}_{[ij]} = [\rho(\mathbf{x}_i - \mathbf{x}_j)]$. At this point, the estimation of the correlation function $\rho(\mathbf{h})$ of $\mathbf{Y}$, on the basis of the observations, has to be faced. However, this is not an easy task since on one hand $\mathbf{Y}$ is not an observed variable and on the other hand it cannot be obtained from the measured variable $\mathbf{Z}$ because the transformation function is non-monotonic.

Regarding modeling, note that $\mathbf{\Gamma}$ has to be a positive semi-definite matrix, then the function ρ has to be a positive semi-definite function. Nowadays, the family of positive semi-definite models includes a wide range of parametric functions, among which users can choose. The maximum likelihood method as well as the rank correlations and the asymmetry of the copulas can be used for the parameters estimation of the selected correlation model. Maximum likelihood is often applied only for the bivariate marginals rather than for the n -dimensional copula (whose density requires the sum of 2^n elements). Indeed, in the former case, the complexity is greatly reduced to the order of n^2 , since observations are paired for computation; however, the existence of independence among different pairs implicitly assumed is not supported by the model. Fitting the rank correlation is often done by graphical inspection or through least squares, analogously to the variogram fitting. If the least squares method is used, then it is necessary to calculate first the sample rank correlations corresponding to the empirical copulas and the theoretical rank correlation can be computed by using the Spearman's rank correlation (Joe 1997)

$$\rho' = 12 \int_0^1 \int_0^1 uv \cdot c(u, v) dv du - 3. \quad (18)$$

Thus, it is minimized, with respect to the parameters of the correlation function, the sum of the squared differences

between the rank correlations of the theoretical and the empirical copulas plus the squared difference of the asymmetries.

Validation of the Copula Models

The goodness of fit of a selected copula model can be assessed by comparing the sample bivariate copulas with respect to the fitted theoretical ones. For this aim, some statistical tests are available in the literature, such as the Kolmogorov-Smirnov distance D_1 or a Cramér von Mises type distance D_2 :

$$D_1 = \sup \left\{ |\hat{C}(u_1, u_2) - C(u_1, u_2)|; (u_1, u_2) \in [0, 1]^2 \right\}, \quad (19)$$

$$D_2 = \int_0^1 \int_0^1 [\hat{C}(u_1, u_2) - C(u_1, u_2)]^2 du_1 du_2. \quad (20)$$

However, performing the test statistics is not straightforward since the independence of samples cannot be assumed. Alternatively, different realizations of random functions having the same multivariate copula can be simulated, so that the assessment of the significance can be obtained by using a bootstrap framework (Efron and Tibshirani 1986). Thus, an algorithm of statistical testing based on **bootstrap**, useful to analyze the suitability of the spatial dependence models, is described hereafter. The validation procedure consists of the following steps:

1. Computation of the sample copulas from the observations on the basis of (12).
2. Parameter estimation of the vector-dependent bivariate copula by using the available sample.
3. Comparison between the sample copula and the theoretical copula, for each distance lag, through the distances D_1 and D_2 . These are indicated with the notation D_1^* and D_2^* .
4. Fixing the counter i equal to zero.
5. Simulating one realization for the multivariate copula related to the sample points. In other terms, the simulation aims to produce a realization for the defining multivariate distribution, then the corresponding multivariate copula is constructed through the formulation given in (14).
6. Calculation of the sample copulas of the simulated field.
7. Computation of the indexes $D_1(i)$ and $D_2(i)$, for these copulas.
8. Increasing the counter i by one.
9. Replication of the previous steps 5–8 until the number H of simulations is reached.
10. Ranking of the distances $D_1(i)$ and $D_2(i)$, $i = 1, 2, \dots, H$, such that $D_j(1) \leq \dots \leq D_j(H)$ with $j = 1, 2$.
11. Rejection of the copula at the level α of significance for the index D_j , if $D_j(i_0) \leq D_j^* \leq D_j(i_0 + 1)$ and $i_0 > H(1 - \alpha)$.

Note that simulating the χ^2 copula is an easy task, since after simulation of the normal $\mathbf{Y}$, then the transformation according to the equation $V_j = Y_j^2$ can be performed.

Vine Copula

In spatial statistics, the interpolation approaches are based on different variants of kriging. However, the choice of assuming that the random field is Gaussian might be too limiting with respect to other more flexible probabilistic models. In this case, the theory of copula can be of some help. Gaussian multivariate distributions have two restrictions: elliptical symmetry and tail independence. This last means that joint extreme events are independent and this is not influenced by the covariance model, while the first limitation implies that pair of high values and pair of low values, at two spatial points, have the same level of dependence. In turn, this characteristic generates smooth interpolation when kriging is used. Thus, using the concept of copula and copula families, which are different from the Gaussian, can overcome these restrictions. The idea, known as the **pair-copula construction**, is to connect bivariate copulas to higher-dimensional vine copulas, through vines (Bedford and Cooke 2002). Since the statistical applicability of vine copulas with non-Gaussian building bivariate copulas was recognized by Aas et al. (2009), vine copulas became a standard tool to describe the dependence structure of multivariate data (Aas 2016). Thus, it is worth introducing first the concept of regular vines from Kurowicka and Cooke (2006).

Definition 1

(Regular vine) A collection of trees $V = (T_1, \dots, T_{d-1})$ is a regular vine on d elements if.

1. T_1 is a tree with nodes $N_1 = \{1, \dots, d\}$ connected by a set of non-looping edges E_1 .
2. For $i = 2, \dots, d$, T_i is a connected tree with edge set E_i and node set $N_i = E_i$, where $|N_i| = d - (i - 1)$ and $|E_i| = d - i$ are the number of edges and nodes, respectively.
3. For $i = 2, \dots, d - 1$, $\forall e = \{a, b\} \in E_i$: $|a \cap b| = 1$ two nodes $a, b \in N_i$ are connected by an edge e in T_i if the corresponding edges a and b in T_i share one node (proximity condition).

A tree $T = (N, E)$ is an acyclic graph, where N is its set of nodes and E is its set of edges. Acyclic means that there exists no path such that it cycles. In a connected tree we can reach each node from all other nodes on this tree. *R-vine* is simply a sequence of connected trees such that the edges of T_i are the nodes of T_{i+1} . A traditional example of these structures are **canonical vines** (C-vines) and **drawable vines** (D-vines) (Aas et al. 2009) in Fig. 2. Every tree of a C-vine is defined by a root node, which has d_i incoming edges, in each tree T_i ,

Copula in Earth Sciences, Fig. 2 (a) *C*-vine and (b) *D*-vine representation for $d = 5$, as given in Aas et al. (2009)

$i \in \{1, \dots, d-1\}$, whereas a *D*-vine is solely defined through its first tree, where each node has at most two incoming edges.

After this brief review of the basic notion of vine, it become easy to introduce the construction of vine copulas to be used in modeling a random field in space or spacetime. In this context, the n -dimensional multivariate distribution to be modeled is referred to the given random field evaluated only at a set of discrete points $\mathbf{x}_1, \dots, \mathbf{x}_n$ (which can be either spatial locations, temporal points, or spatio-temporal points). By following the approach of Gräler and Pebesma (2012); Gräler and Pebesma (2011), bivariate spatial copulas lead to only spatial, only temporal, or spatio-temporal multivariate copulas, differently from the other approaches which have built spatial copulas on the basis of single-family multivariate copulas (Bárdossy 2006; Kazianka and Pilz 2011). Note that a software package is also available on the R environment and is called **spcopula**.

The **pair-copula construction** is based on the idea that multivariate copulas can be approximated with nested bivariate copulas blocks. It is worth to underline that the use of the

term “approximate” is due to the consideration that not all copulas can be rebuild as a vine copula, thus although vine copulas are multivariate copulas, in some cases they can only approximate the target copula.

As well-known the decomposition of the multivariate copula into nested bivariate blocks is not unique, then different decompositions can be obtained from different regular vines, and the choice of the actual vine will depend on the goodness of fit to the multivariate target copula. For the specific spatial and spatio-temporal context, where there is a neighbourhood that can be used to define the decomposition and a central location with respect to which all initial dependencies can be fixed, the canonical vine copula is a reasonable choice. In Fig. 3, a five-dimensional canonical vine is illustrated, although the conditional cumulative distribution functions have been reported without their arguments. The density of the respective pair-copula construction is the product of all bivariate copula densities following the decomposition structure:

$$c(u_0, \dots, u_4) = c_{01}(u_0, u_1) \cdot c_{02}(u_0, u_2) \cdot c_{03}(u_0, u_3) \cdot c_{04}(u_0, u_4) \cdot c_{12|0}(u_1|0, u_2|0) \cdot c_{13|0}(u_1|0, u_3|0) \cdot c_{14|0}(u_1|0, u_4|0) \cdot c_{23|01}(u_2|01, u_3|01) \cdot c_{24|01}(u_2|01, u_4|01) \cdot c_{34|012}(u_3|012, u_4|012), \quad (21)$$

where the recalled conditional cumulative distribution functions $u_{k|V} = F_{k|V}(z_k)$ correspond to partial derivatives of the copulas involved, as specified below

$$u_{k|v} = \frac{\partial C_{jk|v-j}(u_{j|v-j}, u_{k|0..j-1})}{\partial u_{j|v-j}},$$

with v the set of indexes of the conditioning variables and $v-j$ the set of indexes excluding j .

It is worth recalling that the use of vine copulas is advisable not only to model **non-Gaussian random fields** Z (where the non-Gaussianity is referred to marginal distributions), but also to adopt non-Gaussian dependence structure between locations. Then, since every n -dimensional neighbourhood of a random field Z can be interpreted as n -variate distribution, the vine copulas describing these

Copula in Earth Sciences, Fig. 3 Canonical vine structure for the construction of a five-dimensional spatial random field, as given in Gräler and Pebesma (2011)

neighbourhoods need to capture changing correlations across the domain (assuming often isotropy and stationarity), in order to flexibly reflect different neighbourhoods arrangements. To this aim, Gräler (2014) proposed to use blocks of bivariate copulas, which are convex combinations of well-known bivariate copula families whose parameters depend on distance (in space or in spacetime) in the vine copula. These leads to spatial or spatio-temporal vine copulas which are distance-aware. Indeed, an earlier contribution Gräler and Pebesma (2011) highlighted the potentiality of spatial vine copulas for heavily skewed spatial random fields and a first attempt to extend the spatial approach to the spatio-temporal one was given in Gräler and Pebesma (2012). In this way, modeling the dependence structure, in terms of strength and shape, between points in space or in space-time is very flexible. Note that the bivariate space or space-time copulas on the first tree essentially recall a **Gumbel copula**, since it allows for a strong dependence in the tails, differently from the Gaussian case. Moreover, considering marginals together to this vine copula makes a local multivariate probabilistic model of the random field available for prediction at unsampled points. Unlike kriging where each predictive distribution is always Gaussian, the conditional distributions of the covariate vine copula can assume any functional form and then can provide more realistic uncertainty estimates. However, modeling separately marginals and dependence structure offers a wide range of alternatives in the definition of a random field's distribution. Nevertheless, it is crucial to recover reliable models for both components in order to guarantee good results. Simulation from the modeled random function is also practicable and can be performed by using the same package **spcopula**.

For further details on bivariate spatial copulas, where distance is incorporated as parameter, together with the use of many bivariate copula families, the readers can refer to Gräler (2014).

Conclusions

Nowadays, there are wide areas of research that involves relevant theoretical and computational challenges to face interpolation or prediction problems as well as applications in various scientific fields. In particular, some significant lines of research can be found in the construction of new class of models for spatial and spatio-temporal data, as well as in the analysis of big spatial and spatio-temporal data sets or in machine learning methods developed by the computational science researchers.

Correlation and Scaling

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Correlation and scaling (or ranking and scaling, in some publications abbreviated to rascing) is a technique to order stratigraphic events, observed at different locations in a large study region, along a linear scale with variable distances between them. The stratigraphic events considered in applications are mostly biostratigraphic, primarily first or last occurrences of fossil species, but some lithostratigraphic

events can be included as well. These other events may be ash layers, gamma-ray signatures, or other lithostratigraphic events that can be found in different stratigraphic sections across the entire study region considered, which is usually a sedimentary basin.

Correlation Between Sections in Stratigraphy

Correlation of strata on the basis of their fossil content is one of the earliest scientific methods applied in geology. As documented by Winchester (2001), the first geological map was published in 1815 by William Smith under the title: “A Delineation of the Strata of England and Wales, with Parts of Scotland.” It was based on his discovery that strata could be correlated on the basis of their fossil content that changed with time. Shortly afterward, Charles Lyell (1833) in the first edition of his textbook *Principles of Geology* subdivided the Tertiary into different stages by counting how many fossil species they contain are still living today.

Large uncertainties are commonly associated with the positioning of events in biostratigraphic sections. This subject is treated in more detail in the chapter on quantitative biostratigraphy. Here the emphasis is on how scaled optimum sequences can be used for correlation between sections. An artificial example to illustrate uncertainty associated with observed data is shown in Fig. 1. An early statistical method in quantitative stratigraphy was developed by Shaw (1964) for use in hydrocarbon exploration. In this book, Shaw illustrates his technique of “graphic correlation” on first and last occurrences (FOs and LOs) of trilobites in the Cambrian Riley Formation of Texas for which range charts had been published by Palmer (1954). Shaw’s method consists of constructing a “line of correlation” on a scatter plot showing the FOs and LOs of taxa in two sections. If quality of information is better in one section, its distance scale is made horizontal. FOs stratigraphically above and LOs below the line of correlation are moved horizontally or vertically toward the line of correlation in such a way that the ranges of the taxa become longer. The reason for this procedure is that it can be assumed that observed lowest occurrences of fossil taxa generally occur above truly highest occurrences and the opposite rule applies to highest occurrences. Consequently, if the range of a taxon is observed to be longer in one section than in the other, the longer observed range is accepted as the better approximation. The objective is to find approximate locations of what are truly the first appearance datum (or FAD) and last appearance datum (LAD) for each of the taxa considered. True FADs and LADs probably remain unknown, but, by combining FOs and LOs from many stratigraphic sections, approximate FADs and LADs are obtained and the intervals between them can be plotted on a range chart.

Correlation and Scaling, Fig. 1 This artificial example shows three stratigraphic sections in which three fossil taxa (a, b, and c) were observed to occur. Each taxon has first and last occurrence (FO and LO) labeled 1 and 2, respectively. Consequently, there are six stratigraphic events in total. The equidistant horizontal lines represent five regularly spaced sampling levels. The discrete sampling procedure changes the positions of the FOs and LOs. Any observed range for a taxon generally is much shorter than its true range of occurrence. In this example, the observed ranges become even shorter because of the discrete sampling. FOs and LOs coincide in three places. In reality, the FO of a taxon always must occur stratigraphically below its LO. It is because of the sampling scheme that these two events can occur at exactly the same level in this example (see circles in Fig. 1). For comparison, coincident FO and LO would occur in land-based studies when only a single fossil for a taxon would be observed in a stratigraphic section. In this artificial example, it is assumed that all three taxa occur in each section. In practical applications, many taxa generally are missing from many sections

Two sections usually produce a crude approximation, but a third section can be plotted against the combination of the first two, and new inconsistencies can be eliminated as before. The process is repeated until all sections have been used. The final result or “composite standard” contains extended ranges for all taxa. Software packages in which graphic correlation has been implemented include GraphCor (Hood 1995) and STRATCOR (Gradstein 1996). The method can be adapted for constructing lines of correlation between sections (Shaw 1964). Various modifications of Shaw’s graphic correlation technique with applications in hydrocarbon exploration and to land-based sections can be found in Mann and Lane (1995). An example of Shaw’s original method will be given later in this chapter for comparison with two other methods of biostratigraphic correlation.

In another type of approach, Hay (1972) used stratigraphic information on calcareous nannofossils from sections in the California Coast Ranges as an example of application of his method of ordering biostratigraphic events. Hay’s objective was to construct a so-called optimum sequence of FADs and LADs. His example will be discussed in more detail in the next section, because it inspired the “rascing” approach for ranking and scaling later advocated by Gradstein and Agterberg (1982, also see Gradstein et al. 1985) to solve the same problem. In rascing, Hay’s optimum sequence is followed by scaling that consists of estimating intervals of

variable length between the successive events. Scaling can be regarded as a refinement of ranking. The computer program RASC (for latest version, see Agterberg et al. 2013) performs rascing calculations followed by construction of lines of correlation between sections with graphical displays of results.

In their chapter on quantitative biostratigraphy, Hammer and Harper (2005) present separate sections on five methods of quantitative biostratigraphy: (1) graphic correlation, (2) constrained optimization, (3) ranking and scaling (RASC), (4) unitary associations, and (5) biostratigraphy by ordination. Theory underlying each method is summarized by these authors, and worked-out examples are provided. Their book on paleontological data analysis is accompanied by the free software package PAST (available through <http://www.blackwellpublishing.com/hammer>) that has been under continuous development since 1998. It contains simplified versions of CONOP for constrained optimization (Sadler 2004) and RASC, as well as a comprehensive version for unitary associations (Guex 1980), a method that puts much weight on observed co-occurrences of fossil taxa in time. For comparison of RASC and unitary associations output for a practical example, see Agterberg (1990).

Examples of Ranking, Scaling, and Correlation

The first example to be discussed is concerned with sequencing of stratigraphic events. Nannoplankton faunozones were sampled in nine sections across California of which three are shown in Fig. 2 (Hay 1972). Stratigraphic information consisting of nine highest occurrences (HI) and one lowest occurrence (LO) of nannofossils was extracted from these sections labeled A-I in Fig. 3. The columns on the right represent a subjective ordering of the ten events and Hay’s original optimum sequence that is an objective ordering based on frequencies of how many times every event occurs above (or below) all other events considered.

Agterberg and Gradstein (1988) took Hay’s approach one step further by estimating intervals between successive events in the optimum sequence. Each frequency f_{ij} was converted into a relative frequency $p_{ij} = f_{ij}/n_{ij}$ where n_{ij} is sample size. This relative frequency was changed into a “distance” D_{ij} by means of the probit transformation: $D_{ij} = \Phi^{-1}(p_{ij})$ (cf. Agterberg 2014). An example of this transformation is as follows. If two events turn out to be coeval in the optimum sequence, their interevent distance in the scaled optimum sequence becomes 0 as it should be. In Fig. 4, the optimum sequence for Hay’s original example is compared with the scaled optimum sequence obtained after subjecting all

Correlation and Scaling,

STRATIGRAPHIC INFORMATION

Correlation and Scaling, Fig. 3 Hay's (1972) example. One last occurrence and nine "first" occurrences of Eocene nannofossils selected by Hay (1972) from the Sullivan Eocene database. Explanation of symbols: δ = LO, *Coccolithus gammatum*; Φ = LO, *Coccolithus eribellum*; Θ = LO, *Coccolithus solutus*; V = LO, *Discoaster cruciformis*; $<$ = LO, *Discoaster distinctus*; Π = LO, *Discoaster*

germanicus; U = LO, *Discoaster minimus*; W = HI, *Discoaster tribrachiatus*; Δ = LO, *Discolithus distinctus*; □ = LO, *Rhabdosphaera scabrosa*. See Fig. 2 for locations of the nine sections (A-I). Some LOs are for nannofossils also found in Paleocene (Sullivan 1964, Table 3). The columns on the right represent subjective ordering of the events and Hay's original optimum sequence. (Source: Agterberg 1990, Fig. 4.2)

Correlation and Scaling, Fig. 4 RASC results for Hay example of Fig. 3 (after Agterberg and Gradstein 1988); (a) ranked optimum sequence; (b) scaled optimum sequence. Clustering of events 1 to 7 in

the dendrogram (b) reflects the relatively large number of two-event inconsistencies and many coincident events near the base of most sections used. (Source: Agterberg 1990, Fig. 6.3)

superpositional frequencies to the probit transformation and representing the result in the form of a dendrogram.

The approach can be taken a further step forward. In Fig. 5, which is for a single section in a larger database, scaled optimum sequence points are plotted against their depths, and a cubic spline curve was fitted to the data points. The points on the curve can be regarded as estimates of expected positions of the transformed relative frequencies. These expected positions of events in different sections can be used for correlation between sections.

Figure 5 is for one of seven sections used by Shaw (1964) who illustrated his original technique of “graphic correlation” on first and last occurrences of trilobites in the Cambrian Riley Formation of Texas for which range charts had been published by Palmer (1954). Shaw (1964) extended his composite standard method to construct correlation lines between sections. Figure 6 shows correlation results for three sections

in the Riley Formation obtained by three different methods: (1) Palmer’s original biozones that were obtained by conventional subjective paleontological reasoning, (2) Shaw’s so-called Riley Composite Standard (SRC) correlation lines, and (3) Agterberg’s (1990) correlation and scaling (CASC) results in which the expected positions of events were connected by lines of correlation. Error bars in Fig. 5 are projections of single standard deviations on either side of probable positions of events obtained by the CASC method. Clearly, uncertainty in positioning of the correlation lines increases rapidly in the stratigraphically downward direction (for further explanation, see Agterberg 1990). Similar results were obtained by the three different methods used.

In another application to a large database (see Fig. 7), the estimated RASC optimum sequence locations are compared with maximum deviations between observed and best-fitting spline curve for 44 offshore wells drilled along the

Correlation and Scaling, Fig. 5 RASC distance-event level plot for Morgan Creek section. Spline curve is for optimum (cross-validation) smoothing factor $SF = 0.382$. (Source: Agterberg 1990, Fig. 9.23)

northwestern Atlantic margin and on the Grand Banks. This example illustrates that the optimum sequence value for a stratigraphic event is the average value of a frequency distribution of observed occurrences (in this example, LOs only). Using the terminology of Shaw, the corresponding LAD occurs at a stratigraphically later position equivalent to about 9 million years in this application. In a later hydrocarbon application, Agterberg and Liu (2008) showed that the LOs for 27 Labrador and northern Grand Banks wells satisfy a bilateral gamma distribution that plots as a straight line on a normal $Q-Q$ plot when the depths of the LOs in any well are subjected to a square root transformation (see Fig. 8). The straight line fitted in Fig. 8 was fitted to the data points shown excluding those on the anomalous bulge near the center of the plot that reflects the discrete sampling method used when the wells were being drilled. For a more detailed explanation, see Agterberg et al. (2007) and Agterberg and Liu (2008).

Summary and Conclusions

First and last occurrences (FOs and LOs) of fossil species in a region are subject to relatively large uncertainties. In general, FOs are observed above their truly first occurrences, and LOs are below their truly last occurrences because the period of time that any fossil species was in existence generally remains unknown. Various methods of quantitative stratigraphy have been developed to reduce uncertainties related to true period of existence, in order to allow regional correlations between estimated positions of stratigraphic events in sections at different locations in a region. The main technique illustrated in this chapter is ranking and scaling (rascing) of observed stratigraphic events in different sections in a region or in deep boreholes in a basin drilled for hydrocarbon exploration. Estimated average FOs and LOs can be used for correlation between different stratigraphic sections. Uniquely identifiable lithostratigraphic events such as ash layers resulting from the same volcanic eruption can be used along with the biostratigraphic information.

Correlation and Scaling, Fig. 6 Biostratigraphic correlation of three sections for the Riley Formation in central Texas by means of three methods. Palmer's (1955) original biozones and Shaw's (1964) R.T.S. value correlation lines were superimposed on CASC (Agterberg 1990) results. Error bars are projections of single standard deviation on either side of probable positions for cumulative RASC distance values

equal to 2.0, 5.0, and 6.0, respectively. A cumulative RASC distance value is the sum of interevent distances between events at stratigraphically higher levels. Uncertainty in positioning the correlation lines increases rapidly in the stratigraphically downward direction. The example shows that the three different methods used produce similar correlations. (Source: Agterberg 1990, Fig. 9.25)

Correlation and Scaling, Fig. 7 Extended RASC ranges for Cenozoic Foraminifera in so-called Gradstein-Thomas database for offshore wells, northwestern Atlantic margin. Letters for taxon 59 on the right represent (a) estimated RASC distance, (b) mean deviation from spline curve, and (c) highest occurrence of species (i.e., maximum for deviation from spline curve). B is shown only if it differs from A. Good “markers”

such as highest occurrence of taxon 50 (*Subbotina patagonica*) have approximately coinciding positions for A, B, and C. Note that as a first approximation it could be assumed that the highest occurrences (c) have RASC distances which are about 1.16 units less than the average position. Such systematic difference in RASC distance is equivalent to approximately 10 million years. (Source: Agterberg 1990, Fig. 8.9)

Correlation and Scaling, Fig. 8 Normal Q - Q plot of first-order square root transformed depth differences for dataset (b). Approximate normality is demonstrated except for anomalous upward bulge in the center of

the plot, which is caused by the use of discrete sampling interval. (Source: Agterberg et al. 2013, Fig. 8b)

Correlation Coefficient

Guocheng Pan

Hanking Industrial Group Limited, Shenyang, Liaoning, China

Definition

Correlation is a term that describes the strength of dependency between two or more variables, which can be continuous, categorical, or discrete. Correlation coefficient is a measure of the degree to which the values of these variables vary in a relevant manner. The measure is generally defined as linear relationships between variables, but it can be readily generalized to take into account other relationships of more complex forms. Correlation analysis provides a means of drawing inferences about the strength of the relationship between variables. It can be more powerful when used jointly with other statistical tools for data analysis and pattern recognitions.

Introduction

The correlation coefficient is a statistical measure of the dependence or association of a pair of variables. When two sets of values move in the same direction, they are said to have a positive correlation. When they move in the opposite directions, they are said to have a negative correlation. The correlation coefficient is used as a measure of the goodness of fit between the prediction equation and the data sample used to derive the prediction equation.

Correlation analysis answers if a linear association between a pair of variables exists. A correlation relationship between variables can be judged either by quantitative methods or through graphical observations. Correlation analysis is meaningful only when there exists a relationship between variables. The method can be parametric or nonparametric depending on the form or style of data that are used in the statistical analysis (Pan and Harris 1990).

In a broad sense, correlation analysis includes the description of the mathematical form of correlation, such as fitting a regression equation, testing the rationality of regression equation, and applying regression model for statistical prediction. Correlation analysis also includes the significance test of

statistical correlation between variables. Correlation analyses are most often performed after an equation relating one variable to another has been developed (Ayyub and McCuen 2011).

Correlation analysis is an extensively used technique that identifies intrinsic relationships in geoscientific, social-economic, and biomedical fields among others. It is also used broadly in machine learning and networking in recent years to identify the relevance of attributes with respect to the target class to be predicted in environmental study (Kumar and Chong 2018).

A formal correlation analysis can be carried out as follows: inspect scatter graphs of variables, select an appropriate mathematical method, calculate correlation coefficient, determine the degree of correlation between the variables, test the statistical significance of correlation, and judge the nature of correlation between variables.

It is also important to understand what correlation analysis cannot do. Correlation analysis does not provide an equation for predicting the value of a variable. It does not indicate whether a relationship is causal or physical. Correlation analysis only indicates whether the degree of common variation is statistically significant.

Scatter Graph

Graphical analysis is the first effective step in examining the relationship between variables. The relationship between a pair of variables can be visualized through plotting of scatter graphs from a set of sample values. A useful intuitive indication of correlation is the extent of the point cloud around the best-fit line when the data are plotted on a scatter graph. Positive correlation is indicated by a clear pattern of points running from down left to up right, while negative correlation is shown by an opposite pattern.

As an illustration, various degrees of variation between two variables (X and Y) are shown in Fig. 1 using a set of artificial sample data (observations) for the variables. Figure 1a represents an extreme case of perfect positive correlation, while Fig. 1b sketches the extreme case of perfect negative correlation. In Fig. 1c there is no correlation at all between the two variables. In Figs. 1d and e, the degree of correlation is moderate to strong, since in these figures, Y generally increases (decreases) as X increases (decreases) though the corresponding changes are not exactly proportional for all the sample values involved. Figure 1f provides an example of weak correlation between the two variables, implying that Y cannot be predicted by X in a satisfactory accuracy.

Correlation Coefficient, Fig. 1 Various degrees of correlation between the variables x and y : (a) perfect positive correlation; (b) perfect negative correlation; (c) zero correlation; (d) strong positive correlation; (e) strong negative correlation; (f) weak correlation

Random Variable

A random variable, either continuous or discrete, is a variable whose value is unknown or a function that assigns values to each of an experiment's outcomes (observations). A random variable has a probability distribution that represents the likelihood that any of the possible values would occur. In probability and statistics, random variables are used to quantify outcomes of a random occurrence or event and define probability distributions of the event. Random variables are required to be measurable and are typically real numbers.

Continuous random variables can represent any value within a specified range or interval and can take on an infinite number of possible values. An example of a continuous random variable is an experiment that involves measuring the grade of gold in a mineral deposit. The random variable can be represented by a capital letter, such as Z (in unit of gram per ton, g/t). Any gold grade value (for example, from drilling in the deposit), usually denoted by lower case letter z_i , is considered as an outcome of this random variable. The gold deposit is called the population of random variable Z , while the collection of gold grades from drillholes and other sampling methods is called a sample of variable Z .

Discrete random variables take on a countable number and categorical assignment of distinct values, which can be ranks of data values, type of a physical object, etc. In mineral exploration, geologists often consider many quantitative geological measurements as discrete geological phenomena. For instance, the size of ore deposits may be expressed in terms of qualitative categories, such as large, medium, and small deposits. Another example is conversion of a continuous variable to a discrete variable through optimum discretization techniques (Pan and Harris 1990).

Population and Sample

It is necessary to introduce some basic statistical concepts including population and sample, prior to discussion of the correlation and other statistical analysis for random variables. Population is the parent of a sample.

Population refers to the collection of all elements possessing common characteristics and sharing certain properties, while the sample is a finite subset of the population chosen by a sampling process. Population can be finite if its total number of elements (N) is finite; otherwise it is considered infinite. A sample is part of population chosen at random

capable of representing the population in all its characteristics or properties. The major objective of a sample is to make statistical inferences about the population.

As an example, a gold deposit can be viewed as a population of gold grade (random variable), which includes all possible sample values within the deposit. In reality, it is almost impossible to analyze gold grade values (outcomes) of all sample points within the deposit. Instead, we often obtain a limited set of sample values that are designed to reasonably represent the distribution of gold grade within the deposit, for example, through a grid drilling. Then the statistical nature of gold grade in the deposit can be estimated by analyzing a sample of the population.

Statistical characteristic of a population, such as a mean and standard deviation, are called parameters; while a measurable characteristic of a sample is called a statistic. The mean and standard deviation of a population are usually denoted by the symbols μ and σ , while the mean and standard deviation of a sample are represented by the symbols $\bar{x}$ and s .

Accuracy of a sample estimation on the statistical characteristics of a population depends on sample size and sampling method. The greater the size of a sample, the higher is the level of accuracy in representation of the population. Sampling is a procedure for selecting sample elements from a population. A common method is called simple random sampling, which satisfies the following conditions: (1) the population consists of a finite number N elements, (2) each element in population cannot be sampled in duplication, and (3) all possible sample observations are equally likely to occur. Given a simple random sample, conventional statistical methods can be employed to define various statistical characteristics of a random variable, such as a confidence interval around a sample mean of gold grade in a mineral deposit.

Basic Statistics

The most commonly used statistic of a random variable x is the sample mean, which is a central tendency descriptor. For n observations of a given sample, the average value is estimated by

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i \quad (1)$$

where x_i is a sample point and $i = 1, 2, \dots, n$.

Variance or standard deviation is another important statistic that measures dispersion around the mean. The population variance of x is defined in terms of the population mean μ and population size N :

$$\sigma^2 = \frac{1}{N} \sum_{i=1}^N (x_i - \mu)^2 \quad (2)$$

where σ is called standard deviation of the population.

In practice, a statistical parameter of population is estimated by its corresponding sample statistic. Given n observations in a sample, the sample variance is estimated by:

$$s_x^2 = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2 \quad (3)$$

where s is called the sample standard deviation.

The unit of standard deviation is always same as the unit of the variable; for example, if the variable is measured in gram per ton (gpt), the standard deviation also has the unit of gpt. For convenience, the variance of a sample can also be calculated using the following alternative equation:

$$s_x^2 = \frac{1}{n-1} \left[\sum_{i=1}^n x_i^2 - \frac{1}{n} \left(\sum_{i=1}^n x_i \right)^2 \right] \quad (4)$$

In the equations of sample variance, note that $n-1$ (not n) is used to compute the average deviation to obtain an unbiased estimate of the variance. This statistic is always nonnegative.

As a generalization of variance for a single random variable, covariance is defined as a measure of linear associations between two random variables x and y . The population covariance between random variables X and Y is defined with respect to the population means μ_x and μ_y as:

$$\sigma_{xy} = \frac{1}{N} \sum_{i=1}^N (x_i - \mu_x)(y_i - \mu_y) \quad (5)$$

where N is the size of population.

Sample covariance, which evaluates how a pair of variables are associated relative to their means in a sample data set, is defined as follows:

$$s_{xy} = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y}) \quad (6)$$

A positive covariance would indicate a positive linear relationship between the variables, and a negative covariance would suggest the opposite.

Another useful statistic of a random variable is called the median value x_m , which is defined as the middle value when the numbers are arranged in order of magnitude. Usually, the median is used to measure the midpoint of a large set of

numbers. The median value can be determined by ranking the n values in the sample in descending order, 1 to n . If n is an odd number, the median is the value with a rank of $(n + 1)/2$. If n is an even number, the median equals the average of the two middle values with ranks $n/2$ and $(n/2) + 1$ (Illowsky and Dean 2018).

Correlation Coefficient

In geosciences, we often need to examine relationships between different variables, such as gold and silver in a mineral deposit. It is always insightful to plot out the scatter graph of the sample observations as the first step, showing a visual relationship between the two variables. Figure 2 is the scatter plot with a sample of 17 observations on gold (x) and silver (y) from a mineral deposit (population) (see Table 1), which clearly reveals that gold and silver are linearly associated or positively correlated except for a couple of outliers.

This correlation can be readily fitted by simple linear regression analysis with exclusion of the two outliers, which is not a subject of this Chapter. Quantification of the linear association between the two variables is the focus in this section.

While the covariance in Eq. (5) or (6) does measure the linear relationship between two random variables, it cannot be conveniently applied in practice since the two variables of interest could have vastly different standard deviations. It is intuitive that the covariance can be better interpreted if its value is standardized to a neat range, such as $[-1, 1]$ by removing the influence of different variances associated with variables. Thus, the Pearson coefficient (also called the product-moment coefficient of correlation) is designed in this manner so that it can be readily utilized to quantify the strength of linear correlation between variables. The Pearson coefficient in the population form is expressed as the following standardized form (Pearson 1920; Chen and Yang 2018):

$$\rho = \frac{\sigma_{xy}}{\sigma_x \sigma_y} \quad (7)$$

The Pearson coefficient is a type of correlation coefficient that represents the relationship between two variables that are measured on the same interval or ratio scale. The Pearson coefficient is suitable to measure the strength of linear associations between two continuous variables.

Numerically, the Pearson coefficient is represented the same way as a correlation coefficient that is used in linear regression, ranging from $[-1, 1]$. A value of $+1$ is the result of a perfect positive relationship between variables. Positive correlations indicate that observations of both variable move in the same direction. Conversely, a value of -1 represents a perfect negative relationship, indicating that the two variables move in the opposite directions. A zero value means no correlation. Note that the Pearson coefficient shows correlation, not necessarily causation.

In practice, the correlation coefficient ρ is estimated by using a sample consisting of a set of observations for the pair of variables (Rumsey 2019). The sample form of the Pearson coefficient is defined as follows:

$$r = \frac{S_{xy}}{S_x S_y} = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}} \quad (8)$$

While Eq. (8) provides the means to calculate values of the correlation coefficient, the following form is more convenient in computation:

$$r = \frac{n \sum_{i=1}^n x_i y_i - (\sum_{i=1}^n x_i)(\sum_{i=1}^n y_i)}{\sqrt{n \sum_{i=1}^n x_i^2 - (\sum_{i=1}^n x_i)^2} \sqrt{n \sum_{i=1}^n y_i^2 - (\sum_{i=1}^n y_i)^2}} \quad (9)$$

This equation is used most often in practice because it does not require prior computation of the means, and the

Correlation Coefficient,

Fig. 2 Scatter graph of observations for variables gold and silver from a drilling program, showing that the two variables are highly correlated except for a couple of outlying points

Correlation Coefficient, Table 1 Observations of gold and silver grades in a mineral deposit

Observation	Gold (gpt)	Silver (gpt)	Note

7	5.5	21.3	Regular sample point
8	5.7	24.0	Regular sample point
9	4.8	19.6	Regular sample point
10	3.5	12.6	Regular sample point
11	4.0	18.8	Regular sample point
12	2.1	7.1	Regular sample point
13	1.6	5.4	Regular sample point
14	3.3	15.3	Regular sample point
15	1.1	1.8	Regular sample point
16	9.5	6.5	Extreme point (outlier)
17	9.1	9.9	Extreme point (outlier)

computational algorithm is easily programmed for a computer (Ayyub and McCuen 2011).

The formula has been devised to ensure that the value of r will lie in the range $[-1, 1]$ with $r = -1$ for perfect negative correlation, $r = 1$ for perfect positive correlation, and $r = 0$ for no correlation at all. Using the previous example in Table 1, the correlation coefficient between gold and silver is calculated to be 0.46. From the scatter plot, two observations (9.5, 6.5) and (9.1, 9.9) are clearly deviated from the general trend of linear association between the two variables. They are called outliers, which can seriously distort the real relationship between the variables. The correlation coefficient is increased to 0.98 when these two outliers are excluded from the sample.

The Pearson correlation coefficient is good to measure the strength of linear associations between a pair of random variables without involvement of other variables. When more than two variables are there in the system, this measure is referred to as the partial correlation between two random variables by ignoring the effect of other random variables. The partial correlation coefficient will give misleading results if there is another random variable that is numerically related to both variables of interest.

Hypothesis Testing

Equations (8) and (9) provide a tool of estimating correlation coefficient between two variables given a sample consisting a set of observations. It is generally true that higher absolute value of correlation coefficient indicates greater correlation between the variables, and vice versa. In many cases,

judgment or decision is necessary to make if the correlation of two variables is statistically significant in addition to the estimate of correlation coefficient. This judgment calls for the tool of hypothesis testing, which is the formal procedure for using statistical measures in the process of decision making.

Hypothesis testing represents a class of statistical techniques designed to extrapolate information from samples of data to make inferences about populations for the purpose of decision making (Ayyub and McCuen 2011). Here t -test is chosen for hypothesis testing on the statistical significance of correlation coefficient. Note that use of t -test requires that population follows a normal distribution and samples are obtained by simple random sampling. If samples differ slightly from normal distribution, t -test is still applicable, but its results will be inaccurate. As the deviation from normality increases, the results become less reliable.

The strength of correlation is generally gauged by how far from zero the value of r lies. A correlation coefficient of zero indicates that there is no linear relationship between the two variables. The t -test aims to answer the question: "Is the population correlation equal to 0?" This question can be answered by hypothesis testing through the following steps (Ayyub and McCuen 2011): (1) formulate hypotheses; (2) select an appropriate statistical model that identifies the test statistic; (3) specify the level of significance, which is a measure of risk; (4) collect a sample of data and compute estimate of the test statistic; (5) define the region of rejection for the test statistic; (6) select the appropriate hypothesis. The t - statistic can be used to test the significance of linear correlation when the sample size n is not very large.

The t -test for correlation coefficient focuses on the statistical significance of correlation between two variables. Since correlation can be positive and negative, the region of rejection will consist of values in both tails. This is illustrated in Fig. 3a, where T is the test statistic that has a continuous probability density function. In this case, the test is called a two-sided test. A one-sided hypothesis test is also needed sometime for the so-called "directional" parameters. The region of rejection for directional test is associated with values in only the upper tail or lower tail of the distribution, as illustrated in Fig. 3b, c.

The foremost step in performing the t - test is to form hypotheses, which are composed of statements involving either population distributions or parameters. Note that hypotheses should not be expressed in terms of sample statistics. The first hypothesis is called the null hypothesis denoted by H_0 , which is formulated as an equality. The second hypothesis is called alternative hypothesis denoted by H_1 , which is formulated to indicate the opposite. The null and alternative hypotheses, which are written both mathematically and grammatically, must express mutually exclusive conditions. Thus, when a statistical analysis of sampled data suggests that the null hypothesis should be

Correlation Coefficient, Fig. 3 Sampling distribution of the t -test statistic, showing the region of rejection (cross-hatched area), region of acceptance, and critical value (t_{α}): (a) two-sided test, (b) lower tail one-sided test, and (c) upper tail one-sided test

rejected, the alternative hypothesis must then be accepted. The following is a formal t -test procedure:

Step 1: Propose hypothesis H_0 , which implies that there is no linear correlation between the two variables when the population correlation coefficient is zero. The alternative hypothesis would indicate the opposite.

$$H_0 : \rho = 0 \quad (10)$$

$$H_1 : \rho \neq 0 \quad (11)$$

It can be shown that for $n > 2$ these hypotheses can be tested using a t -statistic that is given by

$$t = |r| \sqrt{(n-2)/(1-r^2)} \quad (12)$$

where t is a random variable that has approximately a t -distribution with $(n-2)$ degrees of freedom.

Step 2: Choose a level of significance α . Determine a threshold value α for the test and find out the critical value $t_{\alpha/2}(n-2)$ for a two-sided t -test at the threshold from the t -distribution table, which can be found in many text books for statistics, such as Chen and Yang (2018).

Step 3: Calculate the t -statistic using Eq. (12). The calculated t value is compared against the critical value obtained from the t -distribution table at the critical value $\alpha/2$ for a two-sided test or α for a one-sided test.

Step 4: The null hypothesis H_0 is rejected and H_1 is accepted if the calculated t value is greater than the critical value from the t -distribution table, implying that the correlation between the two variables is statistically significant at the significance level α ; otherwise, the correlation is not statistically significant at the same level.

As an illustration, assume the threshold $\alpha = 0.05$ or 5% for a two-sided test. Using the data in Table 1 by excluding the two outliers, t -value is calculated by Eq. (12), which is given by

$$\begin{aligned} t_{\alpha/2} = t_{0.025} &= 0.98 \sqrt{(15-2)/(1-0.98^2)} = 17.76 \\ &> 2.16 \end{aligned} \quad (13)$$

The null hypothesis H_0 is then rejected in this two-sided test, implying that the correlation is considered statistically significant at the level of significance of $\alpha = 0.05$, since the computed $t_{0.025} = 17.76$ value is greater than the critical value $T_{0.025} = 2.16$ given a freedoms of degree $n-2 = 13$.

As stated, the t -test is suitable when sample size is not very large. For a large sample size, other testing options are recommended, such as z – test, the chi – square test, and the f -test, etc.

Rank Correlation

All discussions above focus on correlation coefficient for continuous variables. In practice, however, it is not always necessary, or even possible, when investigating correlation, to draw on the continuous measurements that have been presented so far. An alternative is to work only from the rank positions. In such cases, the data are ranked according to their importance, class, quality, or other factors, using integer numbers $1, 2, \dots, n$. The coefficient of rank correlation can be calculated for a pair of ranked variables x and y .

While it would be possible to use Pearson correlation coefficient r , in the ranked data, there is an alternative measure, which is specially designed for ranked data called the rank coefficient of correlation r_s . It is sometimes known as “Spearman’s coefficient of rank correlation,” which is given below (Spearman 1904; Graham 2017):

$$r_s = 1 - \frac{6 \sum_{i=1}^n d_i^2}{n(n^2 - 1)} \quad (14)$$

where n is the number of all pairs (x_i, y_i) of ranked data and d is the difference between ranks of corresponding values of x and y .

As with the product-moment correlation coefficient, the coefficient of rank correlation r_s , has been devised to ensure that its value lies within the range $[-1, 1]$. The value for r_s can be interpreted in much the same way as the values for r were in the previous section: $r_s = 1$ for perfect positive correlation, $r_s = -1$ for perfect negative correlation, and $r_s = 0$ for no correlation.

As an illustration in a mineral exploration program, it is insightful to examine the relationship between rock type (x) and copper mineralization (y). Past exploration experience and existing geological maps provide evidence of relevancy between the two variables. Thus, rocks can be ranked according to the degree of their relevancy to the mineralization of copper. Table 2 shows the coded data of rock type and copper mineralization intensity from 12 drillhole intervals, which is explained in Table 3. The scatter plot in Fig. 4 reveals a clear positive correlation between copper mineralization and rock type.

Using Eq. (14), the rank coefficient of correlation between copper mineralization and rock type is calculated to 0.94 using the 12 pairs of rank observations drawn from the drillholes. The result, also shown in Table 2, clearly indicates

Correlation Coefficient, Table 2 Coded rock type and copper mineralization

Observation	Rock code	Cu mineralization	d Square
1	2	1	1
2	1	1	0

Altered porphyry	4	High-grade ore	4
Skarn	5		

Correlation Coefficient, Fig. 4 Scatter graph between code of rock type (x) and rank of copper mineralization intensity (y). The graph clearly shows a highly correlated relationship between the two variables

that copper mineralization has a strong association with rock type.

Rock type is represented by numerical code, while copper mineralization is expressed by class numbers representing intensity of mineralization. The definitions of rock type and mineralization class are given in Table 3.

The statistical significance of the rank coefficient can also be judged by hypothesis testing similar to the correlation coefficient. However, testing methods for discrete data differ

from the *t*-test for continuous data. This is not a subject to be discussed here.

Spearman rank coefficient for correlation analysis is a nonparametric method, which has several advantages. The significance test for rank correlation doesn't depend on sample distribution. Another advantage is immune from outliers or extreme values. If the sample size is small, one big outlier can completely distort Pearson's correlation coefficient, leading to wrong conclusions. Spearman rank correlation coefficient is less affected by outliers and its results are more robust. The rank approach provides a natural filter to suppress or remove excessive influence or noises of outliers from the data.

In addition to the Spearman rank correlation coefficient introduced here, other commonly used nonparametric correlation indexes include the contingency coefficient and the Kendall rank correlation coefficient.

Summary

Random variation represents uncertainty. If the variation is systematically associated with one or more other variables, the uncertainty in estimating the value of a variable can be reduced by identifying the underlying relationship. Correlation and regression analyses are important statistical methods to achieve these objectives. They should be preceded by a graphical analysis to determine (1) if the relationship is linear or nonlinear, (2) if the relationship is direct or indirect, and (3) if any extreme events might dictate the relationship.

The Pearson correlation coefficient is defined as a quantitative index of the degree of linear association. Cautions must be taken when the correlation analysis is applied to the real world. The first caution is the preconditions for construction of Pearson correlation coefficient and its *t*-statistic test. Appropriate use of these requires that the distribution of variables involved must be the bell-shaped and that sample is collected from a representative, randomly selected portion of the total population.

Pearson product-moment correlation coefficient only quantifies the degree of linear association between two variables. A high statistical correlation between two variables can give a misleading impression about the true nature of their relationship. A strong Pearson correlation between two variables does not prove that one has caused the other. A strong correlation merely indicates a statistical link, but there may be many reasons for this besides a cause-and-effect relationship. Variables can be associated in temporally, causally, or spatially. For example, gold and silver are often temporally or spatially associated in a mineralization and geological environment. High correlation coefficient values do describe highly physical association between the two metals in this case. The cost of living and wages are a good example of causal relationship.

Pearson correlation coefficient can be readily distorted when outlying observations in the sample are present. A small number of extreme value points can completely alter the statistical significance of linear association, creating spurious correlation outcomes. Outliers or extreme values are common in sampling for variables in the geoscience fields, such as copper in a mineral deposit. Hence, it is wise to perform visual inspection and basic statistical treatments on extreme values in the original data prior to use of Pearson correlation coefficient.

An important assumption of using correlation coefficient and its *t*-test is the bell-shaped or normal distribution of random variables involved. Unfortunately, most metal grades in mineral deposits are distributed in skewed forms with long tails in the upper value side. Instead of following a normal distribution, these variables usually follow some forms of the so-called lognormal distribution. In this situation, it is appropriate to use the log scale of original data in the correlation analysis.

Coupled Modeling

Mohammad Ali Aghighi and Hamid Roshan
School of Minerals and Energy Resources Engineering,
University of New South Wales, Sydney, NSW, Australia

Definition

Coupled modeling refers to translating our understanding of a process involving two or more interacting physical or

chemical subprocesses into a set of governing equations. These partial differential equations are derived either phenomenologically or from fundamental laws. The governing equation of a subprocess is often extended to account for the effect of other interacting subprocesses through additional terms called coupling terms. Coupled models are solved analytically or numerically through one-way coupling, iterative coupling, or fully coupling approaches. The latter refers to simultaneous solution of all governing eqs. A proper characterization of many of the Earth's processes requires coupled modeling. For instance, the process of geothermal energy extraction involves heat transfer, fluid flow, and rock deformation subprocesses. This process requires cold water to be injected into the natural or induced fractures of a hot rock via a borehole so that the injected water picks up the heat and flows back to the surface through another borehole. Pressurized by the injected water, the rock fractures open, thus their flow characteristics alter. Also, the heat exchange takes place between the injected cold water and the hot rock resulting in rock contraction/expansion as well as rising water temperature. Study of such interacting processes requires coupled modeling. A geothermal energy extraction process constitutes at least three governing equations representing rock deformation, water flow, and heat transfer. Coupled modeling provides more realistic insights into the Earth's developments involving significant interacting subprocesses.

Introduction

Geoscience deals with many natural and artificial processes of which those occurring within the Earth's crust are more of interest from an applied standpoint. Although no process in

Earth takes place in isolation, some can be sufficiently modeled in an uncoupled manner if the effect of other interacting processes can be neglected within an acceptable error range. For example, the process of groundwater flow can be perceived as a sole fluid flow problem if the effect of other processes such as rock deformation on flow is negligible. Otherwise, groundwater flow is a coupled process thus requiring coupled modeling. This means that the governing equation of fluid flow must somehow incorporate the effect of rock deformation.

Another example from an applied geoscience perspective is the process of gas production/drainage from shales. This process involves several individual processes such as gas diffusion within the shale matrix, flow of gas within fractures, and the deformation of matrix due to sorption-induced shrinkage. The interaction of these processes (Fig. 1) adds to the complexity of the problem. For example, the shale matrix deformation changes the flow characteristics, which in turn affects the diffusion process within the matrix, thus deforming the shale matrix and bulk. Study of these interacting processes therefore requires coupled modeling (Aghighi et al. 2020).

In order to develop a coupled model, every contributing process needs to be first described in the form of a field eq. A field equation for a specific process is derived through combining constitutive models and conservation laws. The set of field equations representing all contributing processes is then solved using analytical or numerical methods.

Among countless physical and chemical processes occurring in Earth, solid deformation and transport phenomena are more of interest particularly in applied geoscience. Table 1 provides more information on the simple form of these processes. Most Earth developments and transformations involve the interaction of these processes.

Coupled Modeling, Fig. 1 An example of coupled subsurface processes is shale gas production where several interacting subprocesses of deformation, fluid flow, and diffusion type are involved

Coupled Modeling, Table 1 Solid deformation and transport processes

Process category	Solid deformation	Transport phenomena			
Process	Linear elasticity	Fluid flow	Heat transfer	Solute (ion) transfer	Charge transfer
Physics law	Hooke's law	Darcy's law	Fourier's law	Fick's law	Ohm's law
Flux/strain	Strain (ϵ)	Pore fluids flux ($\mathbf{q}$)	Heat flux ($\mathbf{q}_H$)	Solute flux ($\mathbf{f}$)	Charge flux ($\mathbf{i}$)
Potential/field	Displacement	Head (h)	Temperature (T)	Concentration (C)	Voltage (V)
Drive or load	Stress (σ)	Hydraulic gradient	Temperature gradient	Chemical potential gradient	Electrical potential gradient
Material property	Young's modulus (E)	Hydraulic conductivity ($\mathbf{K}$)	Thermal conductivity (κ)	Diffusion coefficient (D)	Electrical resistance (R)
Equation	$\epsilon = \frac{1}{E} \sigma$	$\mathbf{q} = -\mathbf{K} \nabla h$	$\mathbf{q}_H = -\kappa \nabla T$	$\mathbf{f} = -D \nabla C$	$\mathbf{i} = -\frac{1}{R} \nabla V$

Modified after Mitchell and Soga (2005)

When examining a geoscience-related process, it is more convenient and cost efficient to deal with only one individual process rather than a combination of some processes; however, coupled modeling is often inevitable. Natural and manmade problems in geoscience such as plate tectonics, erosion, sedimentary deposition, groundwater flow, geothermal energy extraction, oil and gas production, CO₂ capture and sequestration, storage of radioactive waste, subsidence, fault reactivation, and hydraulic fracturing inherently consist of more than one process. While the fundamentals of each individual process in physics or chemistry are somewhat well understood, an emerging challenge is to enhance our understanding of the coupled processes (Acocella 2015). This challenge cannot be tackled without studies involving coupled modeling.

The following sections describe some of the most common coupled modeling that are encountered in Earth sciences. These coupled modeling cases are explained here for relatively simple yet common situations where materials are isotropic and homogeneous, fluids are single phase, laminar and incompressible, flow is Newtonian, and the relationship between stress and strain is linear, so is that between the change of the fluid content of the porous medium and pore pressure. There are numerous extensions to the following coupled models where nonlinear relationships (e.g., plasticity and viscoelasticity), non-Newtonian flow, compressible fluids (e.g., gas), anisotropy, heterogeneity, among other complexities, are taken into account. These models have been increasingly used in applied geoscience such as geophysics and hydrogeology as well as earth-related engineering disciplines such as civil, petroleum, mining, and environmental engineering.

Hydromechanical Coupling

Hydromechanical coupling refers to the interactions of fluid flow and solid deformation. One of the simplest formulations of the hydromechanical coupling is the linear poroelastic

theory. This theory was developed by Biot (1941) as an extension to the Terzaghi's effective stress law (Terzaghi 1923). Poroelasticity has been reformulated (Rice and Cleary 1976), extended (Skempton 1954), and used in many applications (e.g., Detournay and Cheng 1988). The linear poroelastic theory is based on the following assumptions among others (Biot 1941): (1) there is an interconnected pore network uniformly saturated with fluid (2) the total pore volume is small compared to the bulk volume of the rock, and (3) pore pressure and stresses can be averaged over the volume of rock.

The governing equations of poroelasticity consist of two equations: a fluid flow equation incorporating the effect of solid deformation and a solid deformation equation incorporating the effect of fluid flow. These governing equations can be written in terms of different pairs of unknowns; however, it is more common to write and solve these equations in terms of displacement and pore pressure representing the solid deformation and fluid flow model, respectively.

Solid Deformation Model and Its Coupled Form

The combination of Hooke's law and the equilibrium equation leads to (Jaeger et al. 2007):

$$(\lambda + G)\nabla(\nabla \cdot \mathbf{u}) + G\nabla^2 \mathbf{u} = 0 \quad (1)$$

where λ and G are Lamé's constants and $\mathbf{u}$ is the displacement vector. Incorporating the effect of fluid flow in Eq. 1 yields (compressive stresses are positive) (Jaeger et al. 2007):

$$(\lambda + G)\nabla(\nabla \cdot \mathbf{u}) + G\nabla^2 \mathbf{u} + \alpha \nabla p = 0 \quad (2)$$

where α is the Biot's coefficient and p is the pore pressure. The term $\alpha \nabla p$ is the hydromechanical coupling term.

Fluid Flow Model and Its Coupled Form

The diffusivity equation results from substituting the Darcy's law in the continuity equation (Ahmed 2010):

$$\frac{\partial p}{\partial t} = \frac{k}{\mu \phi c_f} \nabla^2 p \quad (3)$$

where t is time, k is the permeability of the porous medium, μ is the fluid viscosity, ϕ is the solid porosity, and c_f is the fluid compressibility. Equation 3 can be extended to account for the effect of solid deformation as follows (Detournay and Cheng 1993):

$$\frac{\partial p}{\partial t} = \frac{kM}{\mu} \nabla^2 p + \alpha M \frac{\partial}{\partial t} (\nabla \cdot \mathbf{u}) \quad (4)$$

where M is the Biot's modulus. The last term in the right-hand side is the coupling term representing the effect of solid deformation on fluid flow.

The set of Eqs. 2 and 4 is a well-posed mathematical problem including four equations with four unknowns (three displacement components and the pore pressure).

Thermomechanical Coupling

Thermomechanical coupling or thermoelasticity considers the mutual effect of solid deformation and temperature. This coupling is very similar to the poroelastic coupling with the temperature replacing the pore pressure. The set of governing equations of thermoelectricity is as follows (Coussy 1995):

$$(\lambda + G) \nabla (\nabla \cdot \mathbf{u}) + G \nabla^2 \mathbf{u} + 3\alpha_T K \nabla T = 0 \quad (5)$$

$$\frac{\partial T}{\partial t} = \frac{k_T}{\rho c_v} \nabla^2 T + \frac{3K\alpha_T T_0}{\rho c_v} \frac{\partial}{\partial t} (\nabla \cdot \mathbf{u}) \quad (6)$$

where T is the difference between the current and the reference temperature, α_T is the coefficient of linear thermal expansion, K is the bulk modulus and k_T is the thermal conductivity, ρ is the density, and c_v is the specific heat at constant strain. Equation 6 is a diffusion type equation for temperature, which is obtained by introducing the Fourier's law equation into the conservation of energy equation. Note that $3\alpha_T K \nabla T$ is the thermoelastic coupling coefficient. It can be shown that the effect of solid deformation on heat transfer is negligible for typical values of the parameters involved. Therefore, Eq. 6 is reduced to:

$$\frac{\partial T}{\partial t} = \frac{k_T}{\rho c_v} \nabla^2 T \quad (7)$$

Equation 7 is independent of solid deformation and has been analytically solved for different geometries and boundary conditions (Carslaw and Jaeger 1959).

Thermo-Hydromechanical Coupling

Where change in temperature and rock deformation both affect the fluid flow in a porous medium, thermo-hydromechanical coupling is required for modeling of the system. In this case, three governing equations are needed to describe the three processes involved (Charlez 1991):

$$(\lambda + G) \nabla (\nabla \cdot \mathbf{u}) + G \nabla^2 \mathbf{u} + \alpha \nabla p + 3\alpha_T K \nabla T = 0 \quad (8)$$

$$\frac{\partial p}{\partial t} = \frac{kM}{\mu} \nabla^2 p + \alpha M \frac{\partial}{\partial t} (\nabla \cdot \mathbf{u}) - \alpha_{sf} M \frac{\partial T}{\partial t} \quad (9)$$

$$\frac{\partial T}{\partial t} = \frac{k_T}{\rho c_v} \nabla^2 T \quad (10)$$

where α_{sf} is a thermic coefficient.

Chemo-Hydromechanical Coupling

In a chemically active saturated porous system such as shales and clay-rich rocks, three processes are in interaction: solid deformation, fluid flow, and ion transfer. The ion transfer can alter the state of stress around boreholes causing instabilities (Roshan and Aghighi 2011). Clays swell or shrink when they adsorb or lose water because of the differences in chemical potentials of the species in pore fluid and other fluids that the rock is exposed to. These developments lead to changes in permeability, hence the flow pattern as well as the stress distribution in the formation. In an isotropic formation, where other assumptions of linear poroelasticity also hold, the following governing equations constitute a chemo-poroelastic model (Ghassemi and Diek 2002):

$$(\lambda + G) \nabla (\nabla \cdot \mathbf{u}) + G \nabla^2 \mathbf{u} + \alpha \nabla p - \alpha_{uc} \nabla C = 0 \quad (11)$$

$$\frac{\partial p}{\partial t} = \frac{kM}{\mu} \nabla^2 p + \alpha M \frac{\partial}{\partial t} (\nabla \cdot \mathbf{u}) - \alpha_{pc} \frac{\partial C}{\partial t} - \beta_{pc} \nabla^2 C \quad (12)$$

$$\frac{\partial C}{\partial t} = \alpha_{cc} \nabla^2 C - \nabla (JC) \quad (13)$$

where α_{uc} , α_{pc} , β_{pc} , α_{cc} , and J are chemical and flow coefficients elaborated in Roshan and Aghighi (2011). Equations 11 and 12 include the effects of other interacting processes through coupling terms; however, Eq. 13 is independent of the two other processes (i.e., rock deformation and fluid flow), thus can be solved using existing analytical solutions.

Other cases such as chemo-thermo-hydromechanical coupling can be found in Roshan and Aghighi (2012).

Solving Coupled Models

Coupled models can be solved analytically, numerically, or in a hybrid form. Analytical methods are used either to solve the set of governing equations in a closed form or simplify them for a numerical analysis. Even after being reduced in terms of spatial dimensions and simplifying boundary and initial conditions, only a small fraction of coupled models can be solved analytically. Nonetheless, analytical solutions are widely used for gaining useful preliminary insights into the problem through initial simulations and analysis. They are also employed for benchmarking and validation of numerical solutions of the real problem in more complex forms. Function transformations such as Laplace, Fourier, and Hankel transforms as well as differential operator methods are commonly used for solving coupled models analytically (Bai and Elsworth 2000).

Analytical solutions are convenient and simple to use; however, numerical methods can provide solutions for complex geometries and conditions representing more realistic replications of the problem. Numerical methods discretize the space domain into elements and turn the continuous governing equations into finite equations. The finite element method (FEM) (Zienkiewicz and Taylor 2000), the finite difference method (FDM) (LeVeque 2007), and the boundary element method (BEM) (Banerjee and Butterfield 1981) are the most common numerical methods. The FEM is the most capable among the foregoing methods in terms of handling complex geometries and boundary conditions as well as heterogeneity and nonlinearity (Bai and Elsworth 2000).

Coupling Approaches

Coupled models can be solved based on different coupling approaches: partially coupled and fully coupled. In partial coupling, governing equations are solved separately in a certain order with results being passed onto the next solution at each time step. In hydromechanical coupling, for instance, pore pressure can be evaluated first by solving the governing equation of fluid flow. The pore pressure results will be then introduced into the governing equation of rock deformation (geomechanics) to calculate displacements and stresses. The procedure is repeated for other time steps. If there is no iteration involved at each time step, the method is called “one-way coupling” (Longuemare et al. 2002). The effect of geomechanics on fluid flow is not taken into account in one-way coupling approach and the governing equations are solved once at each time step.

If the results are exchanged at each time step in an iterative manner until a convergence criterion is satisfied, the coupling is called iterative. Results of the iterative coupling approach

are obviously more accurate than that of the one-way coupling approach.

Since the interactions of subprocesses take place simultaneously, it is sensible to solve their respective equations concurrently. This is what signifies a fully coupled approach, which provides accurate results without any need for iteration. The fully coupled approach requires less time compared to the iterative coupling. The governing equations, however, often need to be simplified to be suitable for full coupling and meet the requirements of solution procedures.

Summary

Many processes in the earth involve two or more interacting subprocesses. Coupled modeling is required to describe such processes. A coupled model is a set of governing equations characterizing all contributing subprocesses. Governing equations are derived by combining constitutive and conservation laws. Some of the widely occurring coupling processes can be characterized using hydromechanical, thermo-mechanical, thermo-hydromechanical, and chemo-hydromechanical couplings. Coupled models are solved using analytical and numerical models. While analytical models are more convenient to use, numerical models can handle more complex geometries and conditions. Common approaches for solving coupled models are one-way coupling, iterative coupling, and fully coupling methods. In the latter approach, governing equations are solved simultaneously. Solving models in a fully coupled manner has the advantage of requiring less time compared to the iterative approach; however, it is not applicable to all governing equations unless some simplifications are made.

Cracknell, Arthur Phillip

Kasturi Devi Kanniah

TropicalMap Research Group, Centre for Environmental Sustainability and Water Security (IPASA), Faculty of Built Environment and Surveying, Universiti Teknologi Malaysia, Johor Bahru, Malaysia

Fig. 1 Arthur Phillip Cracknell (1940–2021), © Prof. Kasturi Kanniah

Biography

Arthur P. Cracknell passed away in April 2021. He was an emeritus professor at the School of Engineering, University of Dundee, UK, from September 2002 until April 2021. He was one of the pioneers in the field of remote sensing technology and his contribution to the development and advancement of the technology is remarkable. I regard him as my mentor and a dear friend and I am honored to write a biography about him.

Professor Cracknell started remote sensing works in the late 1970s when the field was still in its infancy in the UK. The establishment, development, and operations of the National Oceanic and Atmospheric Administration's Polar Orbiting Environmental Satellites data receiving station in Dundee University in 1978 was the catalyst for the development of remote sensing in the UK. While he was there, Professor Cracknell initiated research on processing and interpreting remote sensing data that was required by a group of environmental scientists and engineers in Dundee for their environmental consultancy works.

Professor Cracknell established and led a very active research group in remote sensing at Dundee University and trained many foreign PhD students including two of the current UTM professors in remote sensing. Most of the

research conducted by his group focused on the modeling of atmospheric transmission and earth surface conditions, development of software to process remotely sensed data, and the environmental application of remote sensing data.

Besides being actively involved in research projects, he also initiated academic programs via summer schools and postgraduate courses. The summer schools played a great role in advancing the application of remote sensing technology within a teaching and research context in many organizations around the world. The MSc program in remote sensing, image processing, and applications produced many undergraduates and postgraduates over the years.

Professor Cracknell's contribution to remote sensing knowledge dissemination through academic journals is noteworthy. In 1983, he became the chief editor of the *International Journal of Remote Sensing* and later the editor of *Remote Sensing Letters*. He published over 300 research papers and over 30 books covering physics and various remote sensing applications. These publications had significant contributions for innovations and potential future research in remote sensing. He is recognized for these contributions through various prestigious awards that he has received.

Since his retirement from Dundee University, he continued as an active scientist and researcher with universities within and outside of the UK. He was a senior visiting professor at UTM, between 2003 and 2019. At UTM he was engaged with teaching courses to undergraduates, co-supervising PhD candidates, reviewing the curriculum of remote sensing programs, delivering talks, and assisting in research activities.

I became acquainted with him since 2009 when I started to work closely on a project related to carbon storage of oil palm trees through which I had an opportunity to learn a lot from him. I have always noticed that he loved working with students and was always willing to discuss their research projects and manuscripts while imparting his knowledge and values to them. Through his academic network, he also assisted many students to secure scholarships and travel grants to present their research findings in international conferences. He helped to link UTM researchers with scholars from many world-renowned universities such as the Tsinghua University in Beijing. The connection later enabled UTM to expand its research collaboration in many other areas. On behalf of UTM, I thank Professor Cracknell for all his contributions.

Since my early interaction with Professor Cracknell, I have been fascinated by his passion in conducting research and scientific writing even after his retirement. In fact, due to his profound dedication for research, he was always willing to travel with his own expenses. I consider Professor Cracknell to be a principled, responsible, and highly motivated scholar and a gentleman. I feel very honored and thankful to have known such a great person and to have coauthored almost 20 journal articles, conference papers, and to have jointly supervised postgraduate students.

Acknowledgment This chapter is dedicated to honoring the late Professor Cracknell for his contribution to the development of remote sensing. He definitely deserves the honor as a remarkable scientist, educator, and individual.

Cressie, Noel A.C.

Jay M. Ver Hoef

Alaska Fisheries Science Center, NOAA Fisheries, Seattle, WA, USA

Fig. 1 Noel A. C. Cressie, courtesy of Prof. Cressie

Biography

Cressie is best known for his work in spatial statistics. In his widely cited, 900- page book, *Statistics for Spatial Data*, Cressie (1991) developed a general spatial model that unified disciplines using geostatistical data, regular and irregular lattice data, point patterns, and sets in Euclidean space. Since the 1980s, he has been a developer of statistical theory and methods, such as weighted least squares (see article on *ordinary least squares*) for fitting variograms (see article on *variograms*), and he has also written on the history of geostatistics (see articles on *geostatistics*, *kriging*). His book contains his contributions, and those of many others, in the field of spatial statistics.

Since the 2000s, Cressie has been actively researching and applying spatiotemporal models using a hierarchical-statistical-framework. He has made groundbreaking innovations in dimension-reduction to make spatial and spatiotemporal modeling computationally feasible for “big data.” He has developed new classes of nonseparable spatiotemporal covariance models (Cressie and Huang 1999) (see articles on *spatiotemporal analysis*, *spatiotemporal modeling*) and used them in many applications in the geosciences. He synthesized this knowledge in the award-winning books

Statistics for Spatio-Temporal Data (Cressie and Wikle 2011) and *Spatio-Temporal Statistics with R* (Wikle et al. 2019). In statistical theory, Cressie is also highly regarded for his fundamental contributions to goodness-of-fit, which provided a new unified view of this classic research field (Read and Cressie 1988) and Bayesian sequential testing (Cressie and Morgan 1993).

Cressie has published 4 books and over 300 articles/chapters/discussions in scholarly journals and edited books. Among numerous awards and fellowships, in 2009, he received from the Committee of Presidents of Statistical Societies (COPSS) one of the highest awards in statistical science—the R.A. Fisher Award and Lectureship. In 2014, Cressie was awarded the Pitman Medal by the Statistical Society of Australia for his outstanding achievements in the discipline of Statistics, and in 2018, he was elected a Fellow of the Australian Academy of Science. Crystallographic texture

Definition

Crystallographic preferred orientation is a multidisciplinary topic of crystallography (solid states physics), mineralogy, mathematics, and materials science and geosciences. Its subject used to be the statistical distribution of the spatial orientations of crystallites (grains) within polycrystalline specimen, a distinct pattern of which is referred to as texture. Since spatially resolving electron backscatter diffraction delivers digital orientation map images, contemporary texture analysis comprises the spatial distribution of grains by means of image analysis and includes intragrain orientation distributions and grain boundary phenomena.

Historical Notes

Analysis of crystallographic preferred orientation or crystallographic texture analysis and its application originate in materials science and have been initiated by Günter Wassermann in the 1930s and largely extended together with Johanna Grewen (Wassermann and Grewen 1962). Single crystals are largely anisotropic with respect to almost all physical properties, one of the best-known examples in geosciences is the anisotropy of thermal expansion of quartz crystals which is for the crystallographic a-axis about twice as large as for the crystallographic c-axis. Thus, directional or tensorial physical properties of polycrystalline materials such as metals, rocks, ice, and many ceramics depend on the statistical distribution of orientations of grains assuming that the orientation of a grain is unique. Vice versa, a grain could be defined as a spatial domain of material support of a unique crystallographic orientation.

The first experiments to determine texture of a specimen of polycrystalline material were done with X-ray diffraction in a texture goniometer and provided integral orientation measurements. A texture goniometer applies Bragg's law

$$2d \sin \theta = n\lambda, n \in \mathbb{N}, \quad (1)$$

to select a feasible diffracting crystallographic lattice plane with interplanar distance d when keeping the angle θ and the wavelength λ fixed. Then a texture goniometer measures the diffracted intensities of the selected lattice planes with their common unit normal crystallographic direction $\mathbf{h} \in \mathbb{S}^2$ aligned with a given but variable macroscopic direction $\mathbf{r} \in \mathbb{S}^2$ referring to the specimen. These intensities are eventually modeled by a bi-directional probability density function $P(\mathbf{h}, \mathbf{r})$ of normals $\mathbf{h}$ of specified crystallographic lattice planes and specimen directions $\vec{r}$, and its equal area projections on the unit disk are called pole figures. In 1965, Bunge and Roe suggested simultaneously (Bunge 1965; Roe 1965) a mathematical approach in terms of a harmonic (Fourier) series expansion to determine a crystallographic orientation density function f from several $\mathbf{h}$ -pole figures. However, their approach was flawed by the same erroneous conclusion that the odd-order harmonic coefficients of an orientation density function are identical to 0, i.e., that the orientation density function is an even function because experimental pole figures are even, $P(\mathbf{h}, \mathbf{r}) = P(\mathbf{h}, -\mathbf{r})$ due to Friedel's law implying that the diffraction experiment (excluding anomalous scattering) itself introduces a center of symmetry whether it is included in the actual crystal symmetry class or not. Their model of the relationship of an orientation and pole probability density function was incomplete in that it missed to account for both directions $\mathbf{h}$ and its antipodal $-\mathbf{h}$. The mistake was abetted by their rather symbolic notation. Numerical realizations of their model in various computer codes led to occurrences of false texture components in the computed orientation density functions, which became notorious as terrifying "texture ghosts" for more than a decade. The riddle was resolved by a proper model accounting for $(\mathbf{h}, -\mathbf{h})$ by Matthies (1979).

In the early 1990s, orientation imaging microscopy has been developed (Adams et al. 1993; Schwartz et al. 2009) based on electron backscatter diffraction (EBSD) providing spatially resolved individual orientation measurements. The spatial reference of these measurements provides the essential prerequisite to model the geometry and topology of grains at the surface of the specimen by means of mathematical approaches and their respective assumptions. Thus, EBSD experiments open the venue to realize Bruno Sander's vision of a comprehensive fabric analysis (Sander 1950) beyond axes distribution analysis including grain size distribution and grain shape analysis as well as various misorientation distributions, grain boundary classification and directional grain boundary distribution, and other instructive entities.

Introduction

The subject of texture analysis is crystallographic preferred orientation, i.e., of patterns of crystallographic orientations in

terms of their statistical or spatial distribution within a specimen. The statistical distributions range from a uniform (or random) texture representing the lack of any preferential pattern, to sharp textures concentrated around a preferred orientation with a deviation of a few degrees, referred to as a technical single crystal orientation. Texture analysis is a field of multidisciplinary interaction of crystallography, mathematics, solid state physics, mineralogy, and materials science, on the one hand, and geophysics and geology, on the other hand. Analysis of crystallographic (preferred) orientation is based on integral orientation measurements with X-ray, neutron, or synchrotron diffraction, or individual orientation measurements with electron backscatter diffraction (EBSD). Integral orientation measurements require to resolve the inverse problem to estimate an orientation density function from experimental pole intensities. The key to derive any reasonable method is to recognize that their relationship can mathematically be modeled in terms of a Funk-Radon transform. Estimation of an orientation density function from given individual orientation measurements is done with non-parametric spherical kernel density estimation. Moreover, spherical statistics applies to analyze EBSD data. Since EBSD results in spatially referenced individual crystallographic orientations, they provide spatially resolved information and can be visualized as orientation maps. Then crystallographic grains can be modeled, and texture analysis can be extended to fabric analysis.

Definitions

An orientation is an element of the special orthogonal group $\text{SO}(3)$ of rotations in $\mathbb{R}^3$ thought of a rotational configuration of one right-handed orthonormal 3-frame, i.e., an ordered basis of $\mathbb{R}^3$, say $\mathcal{K}_S$, with respect to another right-handed orthonormal 3-frame, denoted $\mathcal{K}_C$. The orientation of the 3-frame $\mathcal{K}_C$ with respect to the 3-frame $\mathcal{K}_S$ is defined as the element $g \in \text{SO}(3)$ such that

$$g\mathcal{K}_S = \mathcal{K}_C. \quad (2)$$

Then the coordinate vectors $\mathbf{h}_{\mathcal{K}_C}$ with respect to the 3-frame $\mathcal{K}_C$ and $\vec{r}_{\mathcal{K}_S}$ with respect to the 3-frame $\mathcal{K}_S$ of a unique unit vector $\mathbf{v} \in \mathbb{S}^2$ are related by

$$g\mathbf{h} = \mathbf{r}. \quad (3)$$

Spatial shifts between the 3-frames are not considered.

A crystallographic orientation takes crystallographic symmetry into account. Crystallographic symmetry enables to distinguish mathematically different orientations of a crystal which are physically equivalent. Representing crystallographic symmetry in terms of the point group S_{point} of the

crystal, its crystallographic orientation is defined as the (left) coset $gS_{\text{point}} = \{gq \mid q \in S_{\text{point}}\}$ of all orientations crystallographically symmetrically equivalent to a given orientation g . A comprehensive treatise of rotations and crystallographic orientations is found in (Morawiec 2004). In case of diffraction experiments, not only the crystallographic symmetry but also symmetry imposed by the diffraction itself (Friedel's law) has to be considered. This symmetry is generally described by the Laue group S_{Laue} which is the point group of the crystal augmented by inversion. However, the cosets of equivalent orientations can be completely represented by proper rotations. Likewise, when analyzing diffraction data for preferred crystallographic orientation, it is sufficient to consider the restriction of the Laue group S_{Laue} to its purely rotational part $\tilde{S}_{\text{Laue}}$. Then, two orientations g and $g' \in \text{SO}(3)$ are crystallographically symmetrically equivalent with respect to $\tilde{S}_{\text{Laue}}$ if there is a symmetry element $q \in \tilde{S}_{\text{Laue}}$ such that $gq = g'$. Thus, a crystallographic orientation is a left coset. The left cosets $g\tilde{S}_{\text{Laue}}$ define classes of crystallographically symmetrically equivalent orientations. The set of all cosets is called quotient space.

Two crystallographic directions $\mathbf{h}$ and $\mathbf{h}' \in \mathbb{S}^2$ are crystallographically symmetrically equivalent if a symmetry element $q \in \tilde{S}_{\text{Laue}}$ exists such that $q\mathbf{h} = \mathbf{h}'$. The set of all crystallographically symmetrically equivalent directions $\tilde{S}_{\text{Laue}}\mathbf{h} \subset \mathbb{S}^2$ may be viewed as a set of positive normals sprouting from the symmetrical equivalent crystallographic lattice planes.

A fundamental entity of texture analysis is the statistical distribution of crystallographic orientations by volume (as opposed to number), i.e., of the volume portion of a specimen supporting crystallographic orientations within a given (infinitesimally) small range neglecting its spatial distribution. The statistical distribution is usually represented by an orientation probability density function f almost always falsely referred to as orientation distribution function since the early days of texture analysis in materials science and solid state physics, respectively, cf. (Bunge 1965; Roe 1965). Thus, an orientation density function f models the relative frequencies of crystallographic orientations within a specimen by volume. It is properly defined on the corresponding quotient space $\text{SO}(3)/\tilde{S}_{\text{Laue}}$, i.e.,

$$f(g) = f(gq), g \in \text{SO}(3), q \in \tilde{S}_{\text{Laue}}. \quad (4)$$

Crystallographic preferred orientation may also be represented by a pole density function P modeling the relative frequencies that an element of $\tilde{S}_{\text{Laue}}\mathbf{h} \subset \mathbb{S}^2$ coincides with a given specimen direction $\mathbf{r} \in \mathbb{S}^2$, i.e., one of the crystallographically symmetrically equivalent directions $\tilde{S}_{\text{Laue}}\mathbf{h}$ or its antipodal symmetric direction coincides with a given specimen direction $\mathbf{r} \in \mathbb{S}^2$. Thus, a pole density function satisfies the symmetry relationships

$$P(\mathbf{h}, \mathbf{r}) = P(q\mathbf{h}, \mathbf{r}), (\mathbf{h}, \mathbf{r}) \in \mathbb{S}^2 \times \mathbb{S}^2, q \in \tilde{S}_{\text{Laue}}, \text{ and}$$

$$P(\mathbf{h}, \mathbf{r}) = P(-\mathbf{h}, \mathbf{r}),$$

i.e., it is essentially defined on $\mathbb{S}^2/\tilde{S}_{\text{Laue}} \times \mathbb{S}^2$.

Pole density functions thought of as functions of the variable specimen direction $\mathbf{r}$ parametrized by the crystallographic axis $\mathbf{h}$ are experimentally accessible as pole intensities from X-ray, neutron, or synchrotron diffraction for some crystallographic forms $\mathbf{h}$ and displayed as $\mathbf{h}$ -pole figures. Orientation probability density and pole density function are related to each other by the Funk-Radon transform (Bernstein and Schaeber 2005). Once an orientation density function has been estimated from experimental $\mathbf{h}$ -pole intensities (or from individual orientation measurements), its corresponding fitted pole density function may be computed and displayed as function of $\mathbf{r}$ parametrized by $\mathbf{h}$, or vice versa; the latter are referred to as inverse pole figures where the parameter $\mathbf{r}$ is usually chosen to be one of the axes of the specimen coordinate system.

Estimation of an Orientation Density Function

An orientation density function can be estimated from integral orientation measurements as provided by X-ray, synchrotron, or neutron diffraction experiments in terms of pole figures or from individual orientation measurements as provided by spatially resolving electron backscatter diffraction (EBSD) experiments in terms of orientation maps. Once an orientation density function is estimated sufficiently well, characteristics quantifying its features such as Fourier coefficients, texture index, entropy, modes, volume portions around peaks or fibers, and others can be computed.

Estimation with Integral Orientation Measurements

Up to normalization, the pole intensities $P(\mathbf{h}, \mathbf{r})$ as displayed in pole figures are a measure of the mean density of orientations rotating the elements of $\tilde{S}_{\text{Laue}}\mathbf{h}$ to the macroscopic direction $\mathbf{r}$. The key element of a mathematical model for crystallographic pole density functions is the Funk-Radon transform $\mathcal{R}f$ of an orientation density function f defined on $\text{SO}(3)$. Here, the Funk-Radon transform assigns the mean values of f along geodesics $G \subset \text{SO}(3)$ to f . Any geodesic G can be parametrized by a pair of unit vectors $(\mathbf{h}, \mathbf{r}) \in \mathbb{S}^2 \times \mathbb{S}^2$ as

$$G(\mathbf{h}, \mathbf{r}) = \{g \in \text{SO}(3) \mid g\mathbf{h} = \mathbf{r}, (\mathbf{h}, \mathbf{r}) \in \mathbb{S}^2 \times \mathbb{S}^2\}. \quad (5)$$

Since

$$\bigcup_{\mathbf{h} \in \mathbb{S}^2} G(\mathbf{h}, \mathbf{r}) = \bigcup_{\mathbf{r} \in \mathbb{S}^2} G(\mathbf{h}, \mathbf{r}) = \text{SO}(3), \quad (6)$$

the geodesics provide a double (Hopf) fibration of $\text{SO}(3)$. Then the Funk-Radon transform $\mathcal{R}f$ of f defined on $\text{SO}(3)$ is defined on $\mathbb{S}^2 \times \mathbb{S}^2$ as

$$\mathcal{R}f(\mathbf{h}, \mathbf{r}) = \frac{1}{2\pi} \int_{G(\mathbf{h}, \mathbf{r})} f(g) dg. \quad (7)$$

It is a probability density function if the function f is a probability density function. The Funk-Radon transform $\mathcal{R}f$ possesses a unique inverse (Helgason 1999). Thus, the initial function f can be uniquely recovered from its Funk-Radon transform $\mathcal{R}f$ by its inversion, the numerical inversion being notoriously ill-posed. The question appears how can a one-to-one relationship exist between the function f defined on the three-dimensional manifold $\text{SO}(3)$ and its Funk-Radon transform $\mathcal{R}f$ defined on the four-dimensional manifold $\mathbb{S}^2 \times \mathbb{S}^2$. The affirmative answer is that the Funk-Radon transform is governed by a Darboux-type differential equation, the ultra-hyperbolic differential equation

$$(\Delta_{\mathbf{h}} - \Delta_{\mathbf{r}})\mathcal{R}f(\mathbf{h}, \mathbf{r}) = 0, \quad (8)$$

where Δ denotes the (spherical) Laplace-Beltrami operator and the subscript denotes the variable with respect to which the Laplace-Beltrami operator is applied (Savolova 1994).

Taking means of the Funk-Radon transform, e.g.,

$$\overline{\mathcal{R}f}(\mathbf{h}, \mathbf{r}) = \frac{1}{2}(\mathcal{R}f(\mathbf{h}, \mathbf{r}) + \mathcal{R}f(-\mathbf{h}, \mathbf{r})), \quad (9)$$

a one-to-one relationship between the mean $\overline{\mathcal{R}f}$ and the initial function does not exist. To recover an estimate $\hat{f}$ from $\overline{\mathcal{R}f}$ requires additional modeling assumptions which are mathematically tractable and physically reasonable, e.g., the non-negativity of f .

To account for crystal symmetry, the basic model of a crystallographic pole density function is

$$\chi f(\mathbf{h}, \mathbf{r}) = \frac{1}{\#S_{\text{Laue}} \mathbf{h}} \sum_{\mathbf{n} \in S_{\text{Laue}} \mathbf{h}} \mathcal{R}f(\mathbf{n}, \mathbf{r}), \quad (10)$$

and may be referred to as spherical crystallographic X-ray transform. Of course, it does not possess an inverse, and the inverse problem does not have a unique solution. The complete discrete mathematical model of the experimental intensities is much more involved, e.g., intensities are experimentally accessible for a few distinct crystallographic lattice planes only, effects of partial or complete superposition

of diffracted intensities from different lattice planes, e.g., complete superposition of (hkl) and (khl) of quartz, have to be accounted for by their structure coefficients, and the experimental intensities, actually counts, are usually not normalized. Their normalization requires special attention as the experimental intensities do not cover an entire hemisphere, a problem referred to as “incomplete pole figures.”

All approaches to the numerical resolution of the inverse problem involve truncated infinite or finite series expansion of the orientation probability density function f , e.g., into generalized spherical harmonics given rise to Fourier series expansion, into finite elements or splines, respectively, or into appropriate radial basis functions (Hielscher and Schaeben 2008), and their discretization. The Fourier approach requires truncation of the series and allows to estimate the even Fourier coefficients only, i.e., the kernel of the mean $\overline{\mathcal{R}f}$, Eq. 9, comprises the generalized harmonics of odd order (Matthies 1979). Thus the nonuniqueness of the inverse problem of texture analysis can be quantified that all odd Fourier coefficients remain inaccessible without additional efforts. Finite series expansion into nonnegative radial basis function employs the heuristic that their linear combination is apt to approximate any nonnegative function reasonably well. It is computationally feasible only when spherical nonequispaced fast Fourier transform (Kunis and Potts 2003, Potts et al. 2009) is applied.

Estimation with Individual Orientation Measurements

An EBSD experiment yields Kikuchi patterns to be processed by methods of image analysis or image comparison to result eventually in a set of spatially referenced representatives $g(x_\ell) = g_\ell \in \text{SO}(3)$, $x_\ell \in \mathbb{R}^2$, $\ell = 1, \dots, n$, of crystallographic orientations in $\text{SO}(3)/\tilde{S}_{\text{Laue}}$. Then an orientation probability density function is estimated by nonparametric kernel density estimation, i.e., the superposition of a radial basis function centered at the data g_ℓ , $\ell = 1, \dots, n$,

$$\hat{f}_\kappa(g|g_1, \dots, g_n) = \frac{1}{n} \sum_{\ell=1}^n \Psi_\kappa(\omega(gg_\ell^{-1})), \quad \kappa \in \mathbb{A}, \quad (11)$$

where $(\Psi_\kappa, \kappa \in \mathbb{A})$ is a set of nonnegative radial basis functions with shape parameter $\kappa \in \mathbb{A}$, actually an approximate identity for $\kappa \rightarrow \kappa_0$. While the choice of the radial basis function Ψ is not generally critical in practical applications, the choice of its shape parameter κ controlling the width or bandwidth, respectively, is so. If the kernel is given, heuristics can be applied to optimize its shape parameter with respect to various criteria (Hielscher 2013). Kernel density estimation

assumes independent and identically distributed random orientations with finite expectation and finite variance.

Grain Modeling with Individual Orientation Measurements

Even though the orientation probability density function and its estimate, respectively, referring to a set of crystallographic grains are basic entities of polycrystalline materials, there are many more entities rather referring to grain boundaries or individual grains which are instrumental to describe and quantify features of the fabric of polycrystalline materials.

Modeling the geometry and topology of grains applies heuristic modeling assumptions, some kind of classification of individual orientation measurements into classes of similar orientations, a geometrical segmentation (partition) of the orientation map image, and a data model to represent the geometry and topology of the grains and their boundaries. The basic heuristic modeling assumption is the user's definition of an angular threshold of the misorientation angle of two crystallographic orientations. If the actual misorientation angle exceeds the threshold, the orientations are considered to be different, possibly stemming from different grains and indicating a grain boundary if their locations are adjacent. Straightforward thresholding of pixel-to-pixel misorientation angles does not yield unique grains. There are quite a few numerical approaches to grain modeling. They may differ by the order of procedural steps, e.g., commencing with the segmentation of the orientation map image and then proceeding to threshold controlled amalgamation of the initial segments to crystallographic grains, or the other way round, prioritizing the clustering of similar orientations followed by geometrical modeling. An example of the former approach features the Dirichlet-Thiessen-Voronoi partition of the map image into polygonal cells centered at the locations of the measurements. This partition is based on the modeling assumption that grain boundaries are located at the bisectors of adjacent measurement locations. It immediately implies that grains are composed of adjacent Dirichlet-Thiessen-Voronoi cells (Bachmann et al. 2011). An example of the latter approach is generalized fast multiscale clustering resulting in grains composed of adjacent pixels (McMahon et al. 2013). Both methods apply graph theory to represent the grain model.

Orientation Statistics

It appears tempting to apply statistical analysis and parametric model fit to individual crystallographic orientation data. Statistics of orientations may be seen as generalization of statistics of directions and axes (Downs 1972). The generalization seems straightforward when orientations are thought of in

terms of unit quaternions. The Bingham distribution applies to axes in $\mathbb{S}^2$ as well as to pairs of antipodal quaternions in $\mathbb{S}^3$ (Kunze and Schaebe 2004). Likewise, the Fisher distribution of directions in $\mathbb{S}^2$ can be generalized to the Fisher matrix distribution of matrices in $\text{SO}(3)$. However, the distributions known from spherical statistics do not apply to crystallographic orientations as they cannot represent any crystal symmetry. Symmetry could be imposed on a quaternion or matrix distribution by superposition corresponding to the crystal symmetry class, but they would not be exponential and therefore lose all the distinct properties of exponential distributions like the Bingham or Fisher distribution. Nevertheless, they may be useful to distinguish patterns of preferred crystallographic orientation in terms of their parameters. The effects of mixing by superposition of a distribution are small if the distribution is highly concentrated. High concentrations can be expected if the measurements refer to an individual grain. Then inferential statistics is possible to distinguish the geometrical shape of highly concentrated clusters of crystallographic orientations (Bachmann et al. 2010). Otherwise, native models for ambiguous rotations are required (Arnold et al. 2018).

Estimation of Macroscopic Directional Properties

Given an anisotropic antipodally symmetric property of a single crystal $E_c(\pm \mathbf{h})$ depending on the crystallographic axis $\pm \mathbf{h} \in \mathbb{S}^2$, the corresponding macroscopic property of a specimen $E_m(\mathbf{r})$ depending on the macroscopic direction $\mathbf{r} \in \mathbb{S}^2$ can be computed given the orientation density function f or the even pole density function, respectively,

$$E_m(\mathbf{r}) = \frac{1}{4\pi^2} \int_{\mathbb{S}^2} E_c(\mathbf{h}) \chi f(\mathbf{h}, \mathbf{r}) d\mathbf{h}. \quad (12)$$

For a much more detailed presentation of the topic, the reader is referred to (Mainprice et al. 2011).

Applications of Texture Analysis

Typical Applications in General

In terms of their objective, applications of texture analysis in materials science or geosciences are very different. The prevailing processes forming texture, i.e., distinct patterns of crystallographic preferred orientation, are plastic deformation, recrystallization, and phase transformations. In materials science, texture analysis typically addresses “forward” problems, like what pattern of crystallographic preferred orientation is caused by a given process, and refers to process control in the laboratory or quality control in production to guarantee a required texture and corresponding macroscopic physical properties, e.g., isotropic steel, i.e., almost perfect uniform

distribution, no crystallographic preferred orientation, or high-temperature semiconductors, i.e., an almost perfect “single crystal” crystallographic preferred orientation.

In geosciences, texture analysis is typically applied to the much more difficult “inverse” problem to identify process(es) of a sequence of geological processes which may have caused an observed pattern of crystallographic preferred orientation in rocks or ice. A result of geological texture analysis could be to exclude a geological process or event. In any case, geological texture analysis aims at an interpretation of the kinematics and dynamics of geological processes contributing to a consistent reconstruction, e.g., of the geological deformation history. Geological texture analysis provides otherwise inaccessible insight and proceeding understanding, e.g., differences in the velocity of seismic waves along or across ocean ridges have been explained with textures changes during mantle convection (Almqvist and Mainprice 2017), varying texture may result in a seismic reflector (Dawson and Wenk 2000), and the texture of marble slabs employed as building facades or tombstone decoration is thought to influence the spectacular phenomena of bending, fracturing, spalling, and shattering of the initially intact slabs (Shushakova et al. 2013).

Texture of a Hematite Specimen from the Pau Branco Deposit, Quadrilátero Ferrífero (Iron Quadrangle), Brazil

Some typical steps of an EBSD data analysis have been presented with respect to hematite from a high-grade schistose ore sample from the Pau Branco deposit, Quadrilátero Ferrífero (Iron Quadrangle), Brazil (Schaebe et al. 2012). They include estimation of an orientation probability density function and modeling of grains, and in particular their interplay. A raw orientation map image from EBSD with the Pau Branco specimen is shown in Fig. 1, where crystallographic orientations are assigned to pixels which in turn are color-coded according to the colors defined in the inverse z -pole figure. The initially estimated orientation probability density function and its corresponding pole figures show a pronounced deviation from the familiar symmetric pattern of crystallographic preferred orientation of hematite (Fig. 2). The obvious asymmetry is caused by one single grain, which is peculiar both by size and by crystallographic orientation (Fig. 3). Excluding this particular grain from the orientation probability density estimation yields the expected symmetric pattern (Figs. 4 and 5).

Crystallographic Preferred Orientation, Fig. 1 (a) Raw orientation map image of 316,050 spatially referenced individual orientation measurements with EBSD (left), where pixels supporting orientation g are

(b) color coded according to $g^{-1}z$ in the z -axis inverse pole figure (right), (Schaebe et al. 2012)

Crystallographic Preferred Orientation, Fig. 2 (a) ODF of individual orientations displayed in σ -sections (left) revealing a conspicuous asymmetry best visible in the $\sigma = 10^\circ$ section (left); (b) corresponding

PDFs for crystal forms of special interest (right). The dots mark the modal orientation g_{modal} and their corresponding $r = g_{\text{modal}}h$, (Schaeben et al. 2012)

Crystallographic Preferred Orientation, Fig. 3 Orientation map image of spatially referenced individual orientation measurements with EBSD after corrections involving confidence index (CI), forward scatter

detector signal (SEM), and grain size. The vaguely visible pattern of vertical lines may be reminiscent of specimen preparation (left); (Schaeben et al. 2012)

Crystallographic Preferred Orientation, Fig. 4 Orientation map image displaying grains with respect to an angular threshold of 10° of misorientation and their mean orientation. It should be noted that there is

a conspicuous grain in terms of its blue color coding a peculiar orientation and its size in the upper left of the image, which accounts for 2.4% of the total surface area of the specimen (Schaeben et al. 2012)

Crystallographic Preferred Orientation, Fig. 5 (a) ODF of individual orientations displayed in σ -sections augmented by the mean orientation of conspicuous grain 829 as a green dot visible in the $\sigma = 10^\circ$ section

(left); (b) σ -sections of a recalculated ODF excluding grain 829 and all its properties, augmented by the modal orientation visible in the $\sigma = 10^\circ$ section (right) (Schaeben et al. 2012)

Conclusions

Texture, i.e., a pattern of preferred crystallographic orientation, provides the first order relation of a microscopic anisotropic property of a single crystal to the corresponding macroscopic anisotropic property of the polycrystalline material. Thus, texture is essential in the design of high-tech materials as well as in the recognition of texture-forming processes.

Definition

A cumulative probability plot or a cumulative distribution function (see Rohatgi and Saleh 2015) is defined on real-valued random variables. For a univariate real-valued random variable, it is given by the function $F_X: \mathbb{R} \rightarrow [0, 1]$ such that

$F_X(x) = P(X \leq x)$ for each $x \in \mathbb{R}$. In the case of two or more random variables, i.e., a multivariate real-valued random variable, it is given by the function $F_{X_1, \dots, X_n} : \mathbb{R}^n \rightarrow [0, 1]$ such that $F_{X_1, \dots, X_n}(x_1, \dots, x_n) = P(X_1 \leq x_1, \dots, X_n \leq x_n)$.

Illustration

As the name suggests, for every real number, a cumulative probability plot accumulates the probability that the random variable takes any value less than or equal to the real number. For example, let X be a univariate random variable that takes values 1 with probability $\frac{1}{3}$, 2 with probability $\frac{1}{6}$, and 3 with probability $\frac{1}{2}$. The cumulative distribution function of X is illustrated by Fig. 1. In the case of multivariate distributions, a similar assumption holds, i.e., the accumulation occurs in each random variable separately.

Relation to Probability Density and Probability Mass Functions

In the case of discrete univariate probability distributions, the cumulative distribution function can be written as a possibly infinite summation (as the support of the probability distribution, i.e., the number of values which the random variable attains with positive probability can be countably infinite) of probabilities or the probability mass function (see Rohatgi and Saleh 2015) as follows:

$$F_X(x) = \sum_{x_i \leq x} p(x_i) \quad (1)$$

Cumulative Probability Plot, Fig. 1 The cumulative distribution function of the discrete distribution given in the text is plotted here. The function is discontinuous at three points viz. at $x = 1$, and $x = 3$. The corresponding y values of the cumulative distribution function at these points are identified by marking with a star

where $p(x_i)$ denotes the probability that $X = x_i$ and the summation is over all $x_i \leq x$ such that $p(x_i) > 0$.

Similarly, the cumulative distribution function can be written as an improper integral of the probability density function (see Rohatgi and Saleh 2015) in the case of continuous univariate probability distributions:

$$F_X(x) = \int_{-\infty}^x f_X(t) dt \quad (2)$$

where $f_X(\cdot)$ denotes the probability density function of X .

It is important to note that there exist probability distributions that are neither discrete nor continuous. Such distributions do not possess either probability mass function or probability density function. For example, consider a real-valued random variable Y whose cumulative distribution function is given by:

$$F_Y(y) = \begin{cases} 0 & \text{if } y < 0 \\ 1 - \frac{e^{-y}}{2} & \text{otherwise} \end{cases} \quad (3)$$

Y is neither a discrete random variable nor a continuous random variable. Fortunately, such distributions are rarely used in applications.

Some Important Properties

In this section, some important properties of a cumulative distribution function are mentioned. These properties hold for cumulative distribution function of every probability distribution irrespective of whether the probability distribution is a discrete or continuous or neither.

1. For a univariate random variable, the probability that the random variable takes values between two real numbers can be expressed as a difference of the cumulative probability plot at the end points. Formally, if $a \leq b$ are real numbers, we have

$$P(a < X \leq b) = F_X(b) - F_X(a) \quad (4)$$

In the case of multivariate distributions, a similar property holds. Let $1 \leq i \leq n$ then

$$P(X_1 \leq x_1, \dots, a < X_i \leq b, \dots, X_n \leq x_n) = F_X(x_1, \dots, b, \dots, x_n) - F_X(x_1, \dots, a, \dots, x_n) \quad (5)$$

2. For a univariate random variable, the cumulative distribution function is a nondecreasing function, i.e., if $b \geq a$ are real numbers,

$$F_X(b) \geq F_X(a) \quad (6)$$

Similarly, for a multivariate distribution, the cumulative distribution function is nondecreasing in each of its variables, i.e.,

$$F_X(x_1, \dots, b, \dots, x_n) \geq F_X(x_1, \dots, a, \dots, x_n) \quad (7)$$

3. The cumulative distribution function is right continuous in each of its variables, i.e., if $1 \leq i \leq n$ then

$$\lim_{x \rightarrow a+} F_X(x_1, \dots, x, \dots, x_n) = F_X(x_1, \dots, a, \dots, x_n) \quad (8)$$

4. The cumulative distribution function is bounded by 0 and 1. More specifically, let $1 \leq i \leq n$ then the following hold:

$$\lim_{x_1, \dots, x_n \rightarrow +\infty} F_X(x_1, \dots, x_n) = 1, \quad (9)$$

$$\lim_{x_i \rightarrow -\infty} F_X(x_1, \dots, x_n) = 0 \quad (10)$$

Uses in Statistics

A cumulative distribution function can be used to simulate data from continuous probability distributions. Suppose one can simulate a continuous uniform distribution on the closed interval $[0, 1]$ using a computer, i.e., $u_1, \dots, u_k$ are realizations of $U[0, 1]$ using a pseudorandom number generation process. Let X be a continuous random variable with a theoretically known distribution. Data from X can be generated using the inverse transformation $F_X^{-1}()$ on $u_1, \dots, u_k$, where $F_X()$ denotes the cumulative distribution function of X . In other words, $F_X^{-1}(u_1), \dots, F_X^{-1}(u_k)$ are realizations of X .

Often, in absence of reasonable assumptions on the distribution of data, nonparametric tests based on empirical estimates of the cumulative distribution function are performed to test statistical hypotheses (see Lehmann and Casella 2006;

Lehmann and Romano 2006). For example, Kolmogorov-Smirnov test (see Wasserman 2006) is widely used in applications.

Summary

In this chapter, a cumulative probability plot or a cumulative distribution function is defined for univariate and multivariate probability distributions. These definitions are then illustrated on a discrete probability distribution with finite support. The relation of cumulative probability plot to probability mass function and probability density is described. This is followed by mentioning some important properties of a cumulative probability plot. The chapter is then concluded by mentioning some of its uses in statistical analyses.

Biography

Jack Dangermond was born in 1945 and grew up in Redlands, California, where his parents owned a plant nursery at which he worked from an early age. His education included a B.S., Landscape Architecture, California Polytechnic College – Pomona, 1967; M.S., Urban Planning, Institute of Technology, University of Minnesota, 1968; and M.S., Landscape Architecture, Graduate School of Design, Harvard University, 1969. He studied at Harvard's Laboratory for Computer Graphics and Spatial Analysis (LCGSA) which influenced his founding in 1969, with his wife Laura, of Environmental Systems Research Institute, (now Esri) and also influenced the later development of Esri's ARC/INFO software.

The Dangermonds' vision for Esri was to develop Geographic Information Systems (GIS) software, demonstrate its usefulness by applying it to real problems, and then make it freely available. When this model proved financially infeasible, Esri was incorporated as a privately held, profit-making business; but Esri continues to be the means to realize their vision.

In the 1970s, Esri developed PIOS, the Polygon Information Overlay System, and GRID for raster data, and applied these in project-focused consulting. Esri next developed ARC/INFO (1982); since its release, Esri has focused primarily on GIS software development, leading to ArcGIS (1999 to the present). In 50 years, Esri has grown from a small research institute to a company with a staff of 4000 in 11 research centers and 49 offices around the world. Jack is a leading advocate for GIS, making thousands of presentations to diverse audiences all over the world.

Supporting geoscience, Esri provides research grants and inexpensive software licenses to higher education, and in 2014 donated a billion dollars of software to US schools as part of the ConnectEd initiative. Esri Press publishes GIS-related technical and educational titles. Esri offers online courses and teaching materials. More than 7000 colleges and universities use and teach ArcGIS.

Jack's professional service has included: Committee on Geography, US National Academy of Sciences; National Geographic Society Board of Trustees; National Geospatial Advisory Committee, NGAC; Earth System Science and Applications Advisory Committee, NASA; Science and Technology Advisory Committee, NASA; National Steering Committee, Task Force on National Digital Cartographic Standards; and Executive Board, National Center for Geographic Information and Analysis (NCGIA).

Among the recognitions of his accomplishments are Officer in the Order of Orange Nassau, Netherlands, 2019; Audubon Medal, The National Audubon Society, 2015; Alexander Graham Bell Medal, National Geographic Society, 2010; Patron's Medal, Royal Geographical Society, 2010; Carl Mannerfelt

Medal, International Cartographic Association, 2008; Fellow of ITC, The Netherlands, 2004; Brock Gold Medal for Outstanding Achievements in the Evolution of Spatial Information Sciences, International Society for Photogrammetry and Remote Sensing, 2000; Cullum Geographical Medal of Distinction for the advancement of geographical science, American Geographical Society, 1999; and James R. Anderson Medal of Honor in Applied Geography, Association of American Geographers, 1998. Jack has received 13 honorary doctorates, including: University of Massachusetts, Boston, Massachusetts, 2013; University of Minnesota, Minneapolis, 2008; California Polytechnic University – Pomona, 2005; State University of New York – Buffalo, 2005; and City University of London, 2002.

Data Acquisition

Rajendra Mohan Panda¹ and B. S. Daya Sagar²

¹Geosystems Research Institute, Mississippi State University, Starkville, MS, USA

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

Data acquisition is a process to collect and store information for production use. Technically, data acquisition is a process of sampling signals of real-world physical phenomena and their digital transformation.

Terminology

Analog-to-digital converter (ADC) prepares sensor signals in the digital form.

Data loggers are independent data acquirers.

Digital-to-analog (D/A) converter produces analog output signals.

Electromagnetic spectrum is the wavelengths or frequencies extending from gamma to radio waves.

Resolution is the smallest incremental unit of a signal in the data acquisition system. Resolution is either expressed in bits or percent of full scale, where one part in 4096 resolution represents 0.0244% of full scale.

Radiometers are the instruments used to measure the intensity of electromagnetic radiation in select bands.

Sample rate is the speed at which a data acquisition system gathers data. Unit: sample/s

Sensors or transducers convert physical phenomena to electric signals.

Spectrometers are devices designed to detect, measure, and analyze the spectral phenomena of reflected electromagnetic radiation.

Signal-molding hardware shapes sensor signals to digital forms in an analog-to-digital converter.

Signal conditioning or transmission is an optimization process that modifies sensor signals to a usable form.

Introduction

Data acquisition is a process to collect and store information for production use. Data are newly collected, legacy data, shared, and purchased data. These data include sensor-generated data, empirical data, and other sources. This data acquisition concept started around the early seventies, with the development of software by the International Business Management (IBM) company solely dedicated to data collection. The computing abilities for data acquisition have been improved immensely with better storage capacities and faster processing. Data acquisition involves signal reception and digitization for storage and analysis using computers (Meet et al. 2018). The data acquisition (DAQ) system has three components (OMEGA):

Sensor → Analog-to-digital-conversion → Transmission

Sensors transduce physical values to electric signals, and the sensor-molding hardware converts them to digital values. These digitally modified values undergo noise correction and optimize for several implications. Several programming languages used for obtaining such signals are Assembly, BASIC, C, C++, Fortran, Java, LabVIEW, Lisp, and Pascal. There is also stand-alone DAQ hardware that can process electric signals without a computer, e.g., data loggers and oscilloscopes. The DAQ software processes data from the DAQ hardware to outputs for meaningful uses.

Data acquisition devices are equipped with signal conditioning and analog-to-digital converter. These devices can be wired or wireless and need a computer for data transmission. The wired data acquisition process can be single-ended or differential inputs. Interface buses like RS232 and RS485 are popular DAQ devices. RS232 is suitable for small businesses but has limitations of supporting one device for serial communication with the transmissibility of 50 ft. Alternately, RS485 has options for multiple device connectivity and transmission support for a distance of 5000 ft. General Purpose Interface Bus (GPIB) or IEEE 488 (as per ANSI protocol) are standard interface buses. The Universal Serial Bus (USB), Ethernet, and PCI are other data acquisition devices, with USB being advantageous for its higher bandwidth and power supply capability. Data acquisition devices vary depending on the data collection speed of the analog-to-digital

converter. This speed is the number of channels sampled per second and expressed as the *sample rate*. DAQ cards or boards increase the sample rate by directly connecting to the bus. In addition, modular data acquisition systems, designed for a high channel count, integrate and synchronize multiple sensors with multiple applications to increase the speed of data collection. The PXI is a popular modular system with tremendous flexibility. It has options of channel count and is cost-effective. This modular system is easy to use and is capable of fast data acquisition. Some data acquisition tools for specific uses by the users are WINDAQ, ActiveX, DATAQ, Flukecal, MSSATRLABS, DAQami, TracerDAQ, DASYPAL, and LabVIEW.

Remote Sensing Data Acquisition

Principles

Remote sensing is a process of data acquisition on earth or other planetary systems. It involves data capture and interpretation of the electromagnetic spectrum without making physical contact with the object. It works on the principle of the law of conservation of energy, i.e., total energy to be conserved over time (Feynman 1970):

$$\text{Incident energy} = \text{Reflected energy} + \text{Absorbed energy} + \text{Transmitted energy}$$

Types

Usually, remote sensing satellites follow three orbital paths: polar, nonpolar, and geostationary (Zhu et al. 2018). *Polar satellites* are placed about 90° above the equatorial plane to procure information about the entire globe and polar regions. These are sun-synchronous satellites appearing at the exact location at the same time for every cycle. They move from south to north and north to south, which explains their ascending and descending nature.

Nonpolar satellites are at lower orbits, i.e., 2000 km from the earth's ground. These satellites provide partial coverage, for example, the Global Precipitation Measurement (GPM) mission satellite covers 65°N to 65°S latitude.

Geostationary satellites are placed above 36,000 km of the earth's surface, very powerful in weather forecasting. These satellites follow the earth's rotation at the same speed the earth rotates. Due to the same reason, these satellites capture the same view of earth's particular area with each observation in a regular fashion.

Sensors

The chief component of remote sensing data acquisition is the sensors, which can be active or passive. *Passive sensors* are capable of detecting solar radiation that is reflected or emitted by the object or scene being observed (NASA) and have radiometers and spectrometers operating in the visible

(400–700 nm), infrared (700–3000 nm), thermal infrared (3000 nm–1 mm), and microwave (1 mm–300 cm) portions of the electromagnetic spectrum (Elert 1998). These sensors are useful in procuring information from land and sea surface, vegetation, cloud, aerosol, and other physical phenomena. Passive sensors are not efficient in penetrating dense clouds, which active sensors can fulfill.

Active sensors do not depend on sunlight for emissivity. These sensors primarily operate in the microwave portion of the electromagnetic spectrum having radio detection and ranging (radar) sensors, altimeters, and scatterometers. Active sensors measure the vertical profiles of aerosols, forest structure, precipitation and winds, sea surface topography, and snow cover. Synthetic aperture radar (SAR) is a well-known active sensor, which provides cloud-free data. Its sensors are capable of collecting data day and night (Woldai 2004).

Resolution

The remote sensing data include multispectral, hyperspectral, optical, Infrared, thermal, and microwave imageries, and their quality depend on four resolution categories: radiometric, spatial, spectral, and temporal (NASA). The satellite resolution varies with the orbits and the type of sensors.

The radiometric resolution provides energy information of a pixel in bits. The higher the bit value, the higher the pixel information, and the higher the radiometric accuracy of the sensor (Liang and Wang 2019). For example, an 8-bit resolution has an extent of digital numbers from 0 to 255 against an 11-bit from 0 to 2047 and so on.

Spatial resolution represents the pixel size of a digital image that explains the minimum area coverage of the satellite sensor on the ground. For example, a satellite sensor at a 1-km resolution has a pixel size of 1 km × 1 km. The pixel is a function of orbital altitude, radiation angle, sensor size, and focal length of the optical system. *Swath width* corresponds to the total field of view on the ground. Satellites have different spatial resolutions to accomplish specific purposes (Table 1). Based on pixel size, satellite sensors have four major spatial resolution categories: (a) coarse (>1 Km), (b) medium (100 m–1 km), (c) high (5–100 m), and (d) very high (<5 m). The lesser the pixel size, the higher the image information and vice-versa. The image quality reduces from a finer to a coarser spatial resolution and vice versa (Fig. 1).

Spectral resolution represents the number of spectral bands captured by a sensor. It helps users to differentiate objects by identifying their spectral signature. Spectral signature is the unique feature of an object expressed as a function of its reflectance or emittance to the wavelengths of the electromagnetic spectrum. The digital images are assigned separate classes of similar pixels by comparing the known spectral signatures in *supervised classification*. Some popular algorithms used for supervised classification are maximum likelihood, minimum distance, principal component analysis, support vector machine, and random forest. Alternately,

images are classified based on their properties without supervision in *unsupervised classification*. Both pixel-based image classification techniques differ from the *object-based image analysis* (OBIA) which groups pixels into representative shapes to their size and geometry.

Temporal resolution is the revisit time of remote sensing satellite to acquire data for the exact location. It depends on the orbital characteristics of the satellite. The frequency of revisiting a location helps to collect information on changes in

forest cover, forest-fire events, glacier melting, flooding, deforestation, and seasonal crop pattern.

Buczowski (2020) provides a comprehensive list of remote sensing satellites and sensors including information about radiometric, spatial, and spectral resolution. More information is gathered using a google search engine and Wikipedia (Table 1). The remote sensing satellite information is categorized based on optical and radar satellites, including their operating organizations or companies. Panchromatic

Conclusions

Data acquisition is an important part of research and data analytics. Understanding its process and use provide valuable inputs for research and management. This is essential for efficiency enhancements in evaluating capacity development and monitoring. With rising demand and complexities in data, the different organizations, industries, and business houses continue to adopt new technological advancements in data acquisition systems. The scope is enormous with the use of big data and simultaneous multitasking.

Data Dictionary

Madhurima Panja, Tanujit Chakraborty and Uttam Kumar
Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

Data dictionary stores catalog information about schemas and constraints, design decisions, usage standards, application program description, user information, etc. that can be

accessed directly by users or the database administrators when needed (Elmasri and Navathe 2000). Such a system is also called an information repository and is a record of the objects in the database (Raschka and Mirjalili 2019). In technological domain, these objects are referred to as metadata. As per the IBM Dictionary of Computing, data dictionary is defined as “centralized repository containing information of the data in the database such that the meaning, relationship, source of the data, where it will be used and the format is clearly mentioned or specified” (McDaniel 1994). In other words, a data dictionary is often termed as a data definition matrix, which is a textual description of data objects and their interrelationships. It is commonly used in confirming data requirements and for database developers to create and maintain a database system. More precisely, a data dictionary describes the physical attributes of the elements of a database such as meaning, relationships to other data, responsibility, origin, usage, allowable values, and format. A data dictionary utility is similar to the database management system (DBMS) catalog, but it includes a wider variety of information and is accessed mainly by users rather than by the DBMS software. Modern businesses rely on database systems that have built-in active data dictionaries and documentations generated with rational DBMSs (e.g., SQL, Oracle, MySQL).

Introduction

In the era of digitization, data is a strategic resource used for scientific research, business management, design of public policies, and many forms of human organizational activity (Batini et al. 1990). A large volume of data generated in the real-world activities falls under the umbrella of big data due to their volume, velocity, and variety (also known as 3Vs of big data). Data collected from the space falls under the category of Earth and astronomical data. This large volume of dataset is creating new opportunities, revolutionizing the innovation of methodologies and thought patterns in the geographic information science (GIS) domain. It is forming the foundation of basic and applied geoscience research and has the potential to underpin industry programs to discover and develop domestic natural resources in order to fulfill the world’s energy and mineral requirements. By modeling geoscience data, scientists can provide improved predictions of both immediate and long-term potential hazards. The geoscience community has gathered an enormous amount of valuable data, much of which is irreplaceable. These data are a trove of untapped resources awaiting scientists, engineers, educators, and policymakers to consolidate and use the information. The potential usefulness of these data has continued to expand, so has the need for space/storage to support the data preservation. Since the ability to preserve the spatial data has not been done at the same pace as that of its acquisition, various

nations are facing the problem of irretrievability of such valuable information. To overcome this problem of data loss, majority of the data are now stored in a centralized DBMS. The metadata of these DBMS, which include supporting information about the database, are then provided through a well-documented data dictionary. Data dictionary is a repository of all types of data produced, managed, exchanged, and maintained in a database represented in a way that allows all users of the information system to understand their meanings.

In other words, database system maintains a description of all the data that it contains. For example, a relational DBMS maintains information about every relation and index that it contains. Similarly, a DBMS also maintains information about views, for which no tuples are stored explicitly. Actually, a definition of the view is stored and is used to compute the tuples that belong in the view when it is queried. This information is stored in a collection of relations maintained by the system called *catalog relations* or *system catalog* or *data dictionary* or *metadata*, that is, not data, but descriptive information about the data. The information in the data dictionary that is metadata about the structure and schema of the database is used for query optimization (Ramakrishna and Gehrke 2000). The data dictionary may also note the storage organization (sequential, hash or heap) of relations, and the location where each relation is stored (Silberschatz et al. 2006). So, a data dictionary is a system database in its own right rather than a user database containing data about the data. All of the various schemas and mapping (external, conceptual, etc.) and various security and integrity constraints are stored in the metadata (Date 2000).

These dictionaries make users aware of various aspects of the data and reduce their dependencies on the database managers/administrators. In the absence of a data dictionary, a user with no prior knowledge might lose the data indefinitely as they may not know the precise location of the data in the database, and ironically this makes it an inevitable part of the database. Therefore, a data dictionary consists of names, definitions, and attributes of data elements to be used or captured in a database, information system, or part of a scientific research. A data dictionary also provides metadata about data elements. The usefulness of data dictionary could be the following among many others:

1. Assisting in providing data consistencies during the project.
2. Using data by multiple users or members of the project.
3. Making data easier to handle and analyze.
4. Enforcing the use of data standards.
5. Cataloging and communicating the structure and content of data among all the users.

Types of Data Dictionary

Data dictionaries can be broadly classified into two main categories – active data dictionary and passive data dictionary – with different purposes.

Active Data Dictionary

Sometimes the structure of the database has to be changed; these changes include removing some old attributes and adding some new ones. If these changes are updated automatically in the data dictionary by DBMS, then the data dictionary is said to be active. Active data dictionary is also known as integrated data dictionary.

Passive Data Dictionary

The data dictionary that is not part of and managed by DBMS is called a passive data dictionary. In this dictionary, any changes in the database are updated manually or by a directed software. These are also known as nonintegrated data dictionary. There are different types of passive data dictionary, which are described next.

Document or spreadsheet: The simplest database technology, spreadsheet, is often used for creating a data dictionary. The Excel data dictionaries are mostly considered to be a passive one due to the lack of built-in technology that can automate database-to-data dictionary encoding. However, one can automate this encoding for some sections of the dictionary using a user-defined function.

Data catalog: A data catalog provides an illustration of the metadata. It is quite user-friendly than any active data dictionary, however, building such a dictionary is quite laborious.

ETL metadata repositories: This data dictionary is created by extract, transform and load (ETL) technique, i.e., extracting data from multiple sources, transforming them to a similar format and finally, loading them to a central location. Since the abovementioned procedure requires human effort, so it falls under the category of passive data dictionary.

Data modeling tools: Similar to the ETL technique, data modeling also requires data manipulation, however, the way it comes together is different. The data modeler uses various tools to process the data and get the result.

There are certain advantages as well as disadvantages of using passive data dictionary as listed below:

1. Central metadata repository: Unlike the active data dictionaries, the passive ones are not integrated into a database or server. Hence, a single dictionary is sufficient for managing metadata of different databases located on different servers or engines.
2. Unified metadata from various databases: Various DBMS like Oracle, SQL Server, Redshift and others use different catalog tables. Thus, the active data dictionaries for these

databases are quite program-specific and deviate from each other. In case of a passive data dictionary, this problem can be surpassed by creating an ETL metadata repository.

3. Additional metadata: The autogenerated metadata present in the active data dictionaries comprises of trivial information. However, in a passive data dictionary, the user is free to add more relevant information regarding the database.
4. Flexibility: In order to update an active data dictionary, one needs to impact the schema of the database, which is often not possible. Passive data dictionaries overcome this drawback because the metadata can be easily updated without impacting the database.
5. User-friendly access: Since passive data dictionaries are maintained separately outside the database, it does not require the user to access the database for acquiring the metadata, hence they often provide user-friendly interface with search functionalities.

However, there are several downsides to implementing a passive data dictionary, which are stated below:

1. Manual maintenance: The most pronounced limitation of passive data dictionary is that it requires manual, or independent from DBMS, perpetuation of the metadata to apply all the changes in the database structure.
2. Metadata can be out of sync from database: An immediate consequence of the previous drawback is that the metadata in a passive data dictionary can be at times out of sync from the database.
3. Additional costs: Passive data dictionaries require additional work, which is mostly done by a third-party software; this incurs additional costs.

Now, an overarching question from practitioners' point of view would be: "*Which data dictionary should we use?*" The answer to the question is not straightforward. As we infer from the above-stated discussion, both active and passive data dictionaries have some strengths and weaknesses and should not be treated as contender to each other. In reality, passive dictionaries acquire metadata from their active counterparts, hence, the former can be regarded as an extension of the later.

Components of a Data Dictionary

Data dictionaries are almost always stored in a tabular format similar to that of a database itself. The attributes or fields of the data are listed as rows in the dictionary, and the columns comprise an element of useful information about the attributes. A detailed description of these components that can be included in a data dictionary is listed below:

- *Attribute name*: A string that identifies the attribute uniquely.
- *Optionality*: It specifies whether information is required in an attribute before a record can be saved.
- *Data type*: It describes what type of data is allowable in a file. Usually, the frequently used data types include numeric, time, string, Booleans, look-ups, and unique identifiers.
- *Data source*: It provides information regarding the origin of the data.
- *Maximum length*: It specifies the cardinality of the attribute.
- *Default values*: In any database, a user might change the data type of any attribute. A usual practice is to keep a track of the original data type to maintain data integrity.
- *Last updated on*: It indicates the date on which the data was last updated.
- *Ownership*: Multiuser-friendly database usually contains details about the person(s) who is(are) responsible for maintaining and updating the data.
- *Definition*: This element makes the database more user-friendly by providing the descriptive information about the attribute.
- *Calculations*: For derived attributes, this column includes the technical information on how the values have been calculated.
- *Acceptable values*: This column provides some values that are accepted by the attribute.

The above-stated list contains the core elements that are usually available in a data dictionary. However, it is not an exhaustive list, and sometimes a data dictionary might include more additional information based on its domain.

Significance of Data Dictionary

In today's data-driven world, big data are generated by every digital process, gadgets, systems, and sensors. Data dictionary is indispensable for tackling a huge volume of data. According to the International Data Corporation (IDC), the global spent on data initiatives in 2021 was estimated to be \$215.7 billion (Needham [n.d.](#)). In spite of significant investments in data lakes, there is no easy way for users to discover, access, and share data. As an immediate consequence of this, a vast amount of data is left unanalyzed. Usually, the data warehouse is primarily handled by a database administrator who tracks the data collection. However, in the absence of such a moderator, it becomes difficult for the data modelers to simultaneously maintain the database and analyze it. In such a scenario, a data dictionary is appropriate for the users as it provides detailed information regarding the data and assists in planning data collection, project development and other

collaborative efforts. Even though the data dictionary is primarily utilized as a metadata repository, there are several other contributory factors toward the usefulness of a data dictionary that are stated below.

1. **Anomaly detection**: Data dictionary summarizes the minimum or maximum values, count of distinct values, and spots duplicates or questionable data for all the attributes of a database. This summarization is useful for effortlessly identifying data irregularities or missing data in a database.
2. **Evaluate data quality**: Data dictionaries make it easier to create a standard set of variable names and descriptions. This helps operators to understand overall system design and data flow, and to find where data interact with various processes or components.
3. **Accurate data**: Data dictionary furnishes information about the source, ownership, and collection procedure of the data; data become more reliable and trustworthy.
4. **Data transparency**: Data dictionary presents detailed information regarding every entity within a dataset, thus reducing dependencies of its users and helping them use the data in the same way.
5. **Application design**: Application developers can create forms and reports with proper data types and controls, and ensure that navigation is consistent with data relationships using a data dictionary.
6. **Data integration**: The notions of various data elements provided in a data dictionary furnish the contextual understanding needed for deciding how to map one data system to another, or whether to subset, merge, stack, or transform data for a specific use.

Data Dictionary in NLP

With the growth of textual big data, the use of Artificial Intelligence (AI) technologies such as natural language processing (NLP) and machine learning becomes even more imperative. The initial steps of any text mining analysis comprise understanding the data examples. To start with, a word cloud is created by spotting the most frequently occurring words. These words are further mapped with the lexicons of the data dictionary for further analysis. The preciseness of these data dictionary plays a vital role in improving the accuracy of any NLP model. Usually, dictionaries are at the heart of any text mining analysis. In the context of NLP, dictionaries are termed as corpus and are majorly available on the web world. For instance, for a sentiment analysis problem where the aim is to automatically classify text according to the emotion they express, a sentiment analysis dictionary can be useful (Medhat et al. [2014](#)). Such a dictionary comprises of information about the emotions or polarity expressed by words, phrases, or concepts. In practice, a

dictionary usually provides one or more scores for each word. These scores are then used to compute the overall sentiment of an input sentence based on individual words. Some of the popular sentiment analysis dictionaries include SentiWordNet (Baccianella et al. 2010), SentiWords (Gatti et al. 2015), VADER (Hutto and Gilbert 2014), etc.

Data Dictionary in Geoscience

In the field of geoscience, several data dictionaries have been created to study land-cover recognition, remote sensing, and climate change and weather prediction problems (Long and Xinqing 2014). From daily temperatures to the movement of the Earth, drone images to satellite images, Google Maps to solar energy data, all relevant information are captured constituting a large volume of data by private and public organizations (Barclay et al. 2020). Some key examples of data dictionaries from geoscience and Earth science fields widely used in GIS are listed below:

- [Earth Explorer USGS Landsat Data Dictionary](#)
- [U.S. Geological Survey Open-File Report 03-001: Data Dictionary](#)
- [Aerial Photo Single Frames Data Dictionary](#)
- [National Hydrography Dataset Data Dictionary](#)
- [Planetary Science Dictionary \(NASA\)](#).
- [MODIS Level 1B Products Data Dictionary \(NASA\)](#).
- [Data Dictionary for Organic Carbon Sorption and Decomposition in Selected Global Soils \(ORNL\)](#).
- [Human Health Risk Assessment Data Dictionary \(ORNL\)](#).
- [Climate and Forecast Conventions Standard Name Table](#)
- [Data Dictionary for the National Database of Deep-Sea Corals \(NOAA\)](#).
- [National Elevation Dataset \(NED\) Data Dictionary](#)

Summary

In this chapter, we have explained how data dictionary is an inevitable part of a DBMS and modern data science. A data dictionary is actually a miniature database stored using special-purpose data structure and code. It is generally preferable to store the data about the database in the database itself that facilitates fast access to the system data. One can refer to a data dictionary in order to understand where a data item would fit in the structure of DBMS. The data dictionary gives vital information about the database in a well-structured manner. Using a data dictionary, any data redundancy (e.g., data duplication) can be easily identified. For multiple members of a research team working with similar data, having a data dictionary facilitates standardization by documenting common data structures and providing the precise vocabulary needed for discussing specific data elements. Shared

dictionaries ensure that the meaning, relevance, and quality of data elements are same for all the users. Data dictionaries also provide information needed by those who build systems and applications that support the data. Among various other applications, data dictionary in geoscience and natural language processing helps modern data scientists to understand the data flow and make robust predictions about the future. The current arena of research in building data dictionary still focuses on completeness that can explain the structure and content of data lakes. Future research on spatial data management system would be more focused on the creation of good quality data.

Data Life Cycle

Fang Huang
CSIRO Mineral Resources, Kensington, WA, Australia

Definition

Data life cycle, or data management life cycle, refers to the whole procedure of data management, starting from the conceptualization of a research question to creating a data product (Fig. 1). In different scenarios, data life cycle models can vary. For example, data sharing is crucial to normal research projects but not so to some sensitive and confidential ones. Based on the comprehensive DCC curation life cycle model (Higgins 2008) and the DDI conceptual model (DDI Structural Reform Group 2004), my proposed generic data life cycle model for mathematical geosciences data includes conceptualization, data collection, data processing, data analysis, data archiving, data sharing, and data product (Fig. 1). These steps are not linear – some steps can be repeated iteratively, and some steps can be further divided into smaller steps. All discussions in this paper mainly focus on research-related scenarios.

Introduction

In the big data era, with the development of scientific instruments and collection methods, the volume, variety, and velocity of data production are increasing at a speed never seen before. It is increasingly important for scientists to come up with tools and data management protocols for conducting research and building scientific collaborations. For example, in high energy physics, the Large Hadron Collider (LHC) accelerator at CERN in Geneva takes 40 million pictures (40 Tb of raw data) per second, which creates an extremely challenging data management problem (Editorial 2018). To deal with data of such a big size, in addition to fast data processing algorithms, a good data management plan is also crucial. A good data management plan will help (1) preserve data provenance and ensure the reproducibility and replicability of scientific projects; (2) make it easier for researchers to access, use and reuse of previously generated data; and (3) enable computers and machines to process data more accurately and efficiently, which becomes increasingly important in the big data era. An overview by Boulton et al. (2012) gives an overview of different data life cycle models.

Conceptualization

Research projects at different scales could emphasize on different steps of data life cycle models. Therefore, before starting data collection, we need to define the scientific goals, the desired results, and expected impacts of the research project. By doing this, we can better design the tools for data collection and processing and find efficient data types for storage. Obviously, these tools are very different among a research group of a few people and an international collaboration program of thousands of people. However, in some cases, we are dealing with problems of so-called “unknown unknowns” – we do not know the problem before some exploratory analysis. Hence, as the “first” step, data conceptualization can always be revisited and revised during the whole data life cycle.

Data Collection

There are generally two ways, usually combined, to collect data – produce data directly and gather data produced by others. Many geoscientists perform instrumental analysis on samples collected by themselves. This is more straightforward because researchers usually know what to expect from sample analysis. Another type is to gather data produced by others. Many published papers, especially old ones, do not have data readily for reuse. Usually, research data will be put as tables in the main text or provided in the supplementary documents. We must use computer programs or scripts to extract and process data from those papers and perform the process later. Another way to get previously published data is to retrieve them directly from data repositories. This way is more efficient with better data quality. A data repository is a set of databases that stores and curates data and provides easy access to users. More discussion can be found in “Data Archiving” and “Data Sharing” sections.

There are existing online tools to help researchers find datasets and data repositories of interest. For example, Google dataset search (datasetsearch.research.google.com) is a tool to discover datasets of interest, both scientific and nonscientific. Google processes and manages metadata from open data repositories and organize them in a way more accessible and findable by users. Another example is Re3data (www.re3data.org), which is a searchable registry of more than 2000 scientific data repositories. The repository registry entries are curated by a group of professionals and update weekly. Datacite (datacite.org) is the global leading provider of persistent identifiers (DOIs) for research data and outputs, where researchers can publish, find, and cite research data. Google dataset search and Datacite lead you directly to the datasets of interest while Re3data provides links to data repositories related to your search keywords. The collected data will be fed into the next step for processing.

Data Life Cycle, Fig. 1 The data life cycle in separate steps and relations

Data Processing

Data processing can have different definitions (Huang 2019), but in this chapter, data processing is defined as the process to clean, combine, and change raw data into the desired form for future analysis. It is said that data processing and preparation usually take 80% of the time of data analysis. After data are collected, we need to examine the dataset and clean up the errors and fix missing values in the data. The examination is sometimes achieved by performing exploratory data analysis, especially for large complex datasets. Depending on the results, we may need to go back to the data collection step to collect more data or even to data conceptualization to redesign the research plan. Data processing is very important and time-consuming. It should not be considered as a single step, but a continuous process that can be revisited during almost all steps throughout the whole data life cycle.

Data Archiving

Data archiving refers to the procedure of moving processed and organized datasets into a data repository, maintaining data provenance and making the datasets accessible to researchers. Data archive takes care of datasets, just like libraries take care of books. There are many existing well-curated data repositories for geoscience research. For example, EarthChem library (www.earthchem.org) hosts a large amount of geoscience analytical data, data syntheses, and even data models. Each dataset will be assigned a DOI for access and citation uses. The GeoBiodiversity database (www.geobiodiversity.com), or GBDB, provides data on stratigraphy and paleontology and enables researchers to conduct research on quantitative stratigraphy, biodiversity dynamics, and paleoecology. The Mindat (www.mindat.org) and Ruff (ruff.info) are both mineralogy repositories, which hosts data including basic mineral properties, origin of samples, formation ages, and even pictures of minerals.

Other than simply being a data curator and provider, data archiving also includes data curation and stewardship, which are key components ensuring the accuracy of the data and enabling the reproducibility and replicability of research projects. More materials can be found in previous studies

(Treloar and Klump 2019). One guideline called “the FAIR data principles” is widely recognized by many research organizations all over the world, including American Geophysical Union (AGU), National Institution of Health (NIH) of the US, European Commission, and countless universities and research institutions. The FAIR principles include the requirements to make data findable, accessible, interoperable, and reusable. Research data that follow these principles will be more easily used and reused by humans, and more machine friendly in terms of automatically finding and processing those data. A comment paper (Wilkinson et al. 2016) gives you a better understanding of the FAIR principles.

Data Analysis

Data Analysis in this chapter refers to the process of using statistical methods and algorithms to extract information from the data. After data processing, we can perform some preliminary analysis to examine the data to determine the next step to take. The data analysis results are then summarized in a data product like a research paper or a report. Typically, data analysis can be divided into exploratory analysis, descriptive analysis, and predictive analysis.

1. **Exploratory analysis:** It is an approach to analyzing datasets to summarize their characteristics, often with visual methods. The primary goal of exploratory analysis is to see if the data can tell us some information before the formal modeling. For example, check the completeness, examine for obvious errors and outliers.
2. **Descriptive analysis:** It usually summarizes the main features of the data. Correlation, classification, and regression analysis can be used to find the patterns and relationships among the data variables. Descriptive analysis, usually aided by data visualization, can help us get a better idea of the data and build hypotheses for next step analysis.
3. **Predictive analysis:** It uses a variety of statistical methods and machine learning algorithms to make predictions based on the trends and patterns found in existing data. In machine learning models, datasets are usually divided into training data and test data, which usually take 80 and

20%, respectively. After the selection of algorithm(s), we can use the train data to tune the parameters of the machine learning models. The test data should be held back from the model training. The performance of trained models can be evaluated using test data to avoid overfitting. There are many well-established ways to randomly select training and test data for unbiased results. With the trained model, we can make predictions on new data collected in the future.

Data Sharing

There are two key reasons for sharing data: (1) for reproducible and replicable scientific research and (2) for future large-scale scientific research by integrating existing research data. According to the “Reproducibility and Replicability in Science” report (National Academies of Sciences and Medicine 2019), reproducibility is “obtaining consistent results using the same input data; computational steps, methods, and codes; and conditions of analysis” and replicability is “obtaining consistent results across studies aimed at answering the same scientific question, each of which has obtained its own data,” in which data are the key component.

Other than reproducibility and replicability, data sharing also plays an important role in enabling new sciences in the future (Editorial 2018). In astronomy and astrophysics, the Large Synoptic Survey Telescope (LSST) being built in Chile will capture images of the night sky, and each night will produce 20TB of data, which will be open to the public (Chahin 2017). Similar situation in which large scientific programs share data publicly also happens in research fields like seismology and meteorology. For economics and biology, there is also a well-developed culture of data sharing – researchers working on genetic sequencing cannot publish papers without submitting related data into specific repositories. Compared to these fields, the situation in geoscience communities is improving but not there yet. The shared data can be feed into data collection by other researchers.

Having said that, research projects with different goals can have distinct requirements on data openness: most published data are completely open while some sensitive projects must be kept confidential. Researchers need to find a balance between confidentiality and public interest or benefits.

Data Product

In the current chapter, data product refers to the product produced by the insights gained from previous data analysis, which can be a scientific paper, a report, or simply a dataset, or a tool, an application, or a model that is useful to the community. As a main data product in research, data publication has been proposed and discussed to be a way to give credits to data creators/collectors (Klump et al. 2006). Due to historical reasons, though they are very time-consuming and labor

intensive, data collecting, processing, and curating are often not as well acknowledged and appreciated as scientific papers. In traditional tenure track evaluation systems, journal papers, scientific grants, community service contributions, student guidance, and teaching performance are all important metrics but not for datasets creation and maintenance. Therefore, data publications become an important data product to fill in this gap. However, unlike static scientific publications, datasets can be evolving constantly as new data are being generated and added, which will cause dataset version issues. The discussion is still on going to find better ways to give dataset creator credits, and this discussion should involve all stakeholders – researchers, funding agencies, universities and institutions, and research organizations.

Summary

In the big data era, data become an increasingly important component in scientific research. A data management model that follows the FAIR principles can increase the efficiency of research collaboration and communication by making data more findable and accessible. By making research more transparent, it can also improve reproducibility and replicability of published research. With the help of machines to automate the collecting, processing, analyzing, and sharing data, novel research with larger scale of data will be made possible. Though many examples in this chapter focus on geoscience data, the discussions should be applicable to other research fields as well.

Data dredging; Data science; Knowledge discovery from data; Knowledge extraction; Machine learning; Pattern analysis

Definition

Data mining is the process of utilizing computer algorithms to discover knowledge and information from large amounts of data. Data mining, often interchangeably used with knowledge discovery from data (KDD), is sometimes viewed merely by others as one critical step of KDD (Fig. 1) (Han et al. 2011). The three essential elements of data mining are data, algorithms, and information (or knowledge). Data mining is interdisciplinary and employs many techniques from statistics, machine learning (ML), database, high-performance computing, and domain disciplines (e.g., geosciences). Here, the domain discipline refers to the field in which data mining is applied to gain knowledge and information. In geosciences, it is also not uncommon that data mining is treated as a synonym for machine learning, although some might argue that machine learning is more focused on the development of computer algorithms that are applied during the workflow of data mining. The major types

of geoscience data that can be mined for information include matrix data, time-series data, network-based data, and geospatial data. Based on the type of information to be mined and the technologies to be applied, data mining tasks can be divided into five categories: association and correlation, classification, regression, clustering, and outlier analysis (Han et al. 2011). Benefiting from the ever-increasing stream of large geoscience data and the improvement of computational resources, the widespread application of data mining in geosciences becomes inevitable. The most promising near-future development of data mining in geosciences is likely the integration of data mining and physics-based modeling (Reichstein et al. 2019).

What Geoscience Data Can Be Mined?

The explosive growth and ever-increased diversity of geoscience data in the past few decades are at least partially attributed to the development of cheap automatic sensor-based monitoring devices that are deployed in the soil, water, and air. Among those large geoscience datasets, major types of data that can be mined include matrix/tabulated, time-series, geospatial, and network/graph-based. There are overlaps among these data types, e.g., all of the latter three types of data can be formatted as matrix/tabulated data.

The matrix/tabulated data is probably the most common data format in geosciences. Matrix data often has two dimensions in which each row represents one sample while each column contains a feature or characteristic of the sample. For example, Tesoriero et al. (2017) compiled a large set of groundwater quality samples including nitrate, iron, arsenic concentrations, and other bedrock and soil characteristics. In this example, each row represents one groundwater sample. Matrix data is intuitive to read. However, it becomes less convenient to use matrix data to illustrate the spatiotemporal trends of data or the intersample relationship. This is why we also need to organize geoscience data in other formats, e.g., time-series, geospatial, and network-based data. These additional data types allow the incorporation of additional spatiotemporal context and the information of the intersample relationship into the stored data.

Time-series data refers to a set of data points indexed in time order. The time when the data point is collected is often used as the timestamp, although other types of timestamps have also been used (e.g., age of rock samples). Time-series data can be formatted as matrix data in which each row represents a sample from a time point and an additional column(s) should be added to show the timestamp of each sample. Time-series data is often used to describe the temporal trend of geoscience parameters. For example, the National Water Information System from the United States Geological Survey (<https://waterdata.usgs.gov/nwis>) hosts time-series

Data Mining, Fig. 1 The view of knowledge discovery from data (KDD) and data mining from the perspective of machine learning and statistics communities

data of water quantity and quality of the water body in the United States.

Geospatial data refers to the geoscience data for which we have information on the geographic location. Similar to time-series data, geospatial data can be formatted as matrix data as well when the location information is added as additional column(s) (e.g., latitude and longitude) in the matrix. In particular, an important source of geospatial data is the remote sensing data from satellites. For example, Google Maps and government agencies provide public access to low- and high-resolution satellite and multispectral imagery.

The last common data type in geoscience is network-based data. Unlike matrix data, network-based data is represented by nodes (vertices) and edges (links; connecting nodes), which can effectively illustrate the relationship between samples. For example, Agarwal et al. (2020) reported a dataset of five geochemical analytes including chloride, bromide, barium, magnesium, and sodium of >80,000 river water samples in a complex river network. Agarwal et al. used the river network-based data to inform the impact of human activities on river water chemistry. Barbier et al. (2020) visualized the compiled data from multiple experimental serpentinization studies into a network with each node representing each experiment and edges indicating the similarity between different experiments.

More and more geoscience data, in particular, the compiled datasets in large size, becomes available nowadays because more geoscience researchers are following the findability, accessibility, interoperability, and reusability (FAIR) principles when sharing data. To comply with FAIR principles, geoscience data should be transformed into a machine-readable format (Wen 2020). Geoscience data can be shared in either discipline-specific or general data repositories. A data repository is a place storing data and providing

access to users (Wen 2020). For example, the HydroClient database (<https://data.cuahsi.org/>) is a popular database in which the hydrology community publishes time-series and geospatial data. Data in the HydroClient database can be downloaded as matrix data. In addition, the Shale Network database (<https://doi.org/10.4211/his-data-shalenetwork>) that is published in the HydroClient compiles water quality data for water samples collected from the regions of oil and gas production. Each of these Shale Network samples has geographic coordinates reported. The PANGAEA database (<https://www.pangaea.de/>) is an example of more general data repositories hosting geospatial data from many subdisciplines of geosciences.

What Methods Are Used in Data Mining?

Data mining tasks include the characterization of the data properties (descriptive task) and predictions for the past or the future by learning from existing data (predictive task). Major data mining tasks introduced below include association and correlation, clustering, outlier detection, and classification and regression. The first three tasks are descriptive while the last one is a predictive task.

The goal of association and correlation (AC) analysis, as a descriptive task, is to assess the association or correlation between parameters. In geosciences, a common correlation task is to evaluate the spatial correlation of two parameters. For example, Wen et al. (2018) reported a compiled ground-water quality dataset from the region of oil and gas production in the state of Pennsylvania in the United States. With the rapid development of oil and gas drilling in the United States, the public is getting concerned about the associated environmental impact, e.g., the groundwater contamination. Wen

et al. applied a geospatial analysis tool (<https://github.com/jaywt/SWGT>) to assess the spatial correlation between methane (the major component of natural gas) in groundwater and the proximity to oil and gas wells. They successfully identified a few localities where some natural gas wells are potentially problematic. In paleoclimatology, scientists have striven to find geochemical proxies that correlate with the level of atmospheric oxygen, and air and sea temperatures to reconstruct the ancient climate.

Cluster analysis is the data mining task of classifying a set of samples in a way that a sample is more similar to samples in the same class than to those in other classes. Cluster analysis is one type of unsupervised learning technique. Unsupervised learning refers to those data mining techniques which discover information in a dataset with no preexisting classes. Unlike unsupervised learning, supervised learning techniques rely on datasets with preexisting classes which are often generated by humans. Cluster analysis is used to generate these previously unknown classes for a dataset. The principle of cluster analysis is to maximize intra-class similarity while minimizing inter-class similarity (Han et al. 2011). Typical clustering techniques include K-Means, spectral clustering, Gaussian mixture, self-organizing map (SOM), and affinity propagation. For example, SOM was previously used to infer distinct but spatially contiguous classes within footwall and hanging, basalts, and andesites (Cracknell et al. 2014).

Outlier analysis (OA) is the task of detecting rare or anomalous sample(s) in a dataset. These rare or anomalous samples often fail to comply with the general rules or patterns of the majority of the dataset. Such samples are called outliers. Two major applications of outlier detection in geosciences include the removal of anomalous data before performing other data mining tasks and the detection of ecosystem disturbances. Zheng et al. (2017) developed an outlier detection algorithm and applied it to water quality data along with relevant contextual features from the regions of oil and gas production to successfully detect groundwater samples likely contaminated by nearby problematic oil and gas well(s). Some examples of these contextual features include the location of water samples, the information about nearby oil and gas facilities, and geologic features (e.g., the distance to faults).

Unlike the above tasks, regression analysis (RA) and classification analysis (CA) are supervised learning techniques and predictive tasks. In RA, data mining algorithms are first used to evaluate the relationship between a target variable and often a set of predictor variables in a dataset (i.e., training data) for which values of both target variable and predictor variables are known, and then applied on another dataset (testing data) for which only values of predictor variables are known to predict the values of target variable of the testing data. Here, the target variable refers to the parameter to be

predicted while predictor variables denote the set of features used in the RA/CA algorithms to make predictions for the target variable. Similar to RA, CA also requires both training data and testing data, while the goal of CA is to predict the classes of the target variable instead of its values. Typical algorithms used in RA and CA include decision trees, random forest, support vector machines (SVM), naïve Bayesian, rule-based classification, logistic/linear regression, and neural networks. For example, Wen et al. (2021) applied the logistic regression method on compiled water quality data of groundwater samples to predict the probability of dissolved methane in groundwater being originated from nearby oil and gas production activities.

Summary and Conclusions

Data mining refers to the process of discovering information from a large amount of data. Driven by the increasing volume, variety, and velocity (3Vs) of geoscience data as well as the advancement in data science techniques, data mining methods have been widely applied in geosciences. The most promising near-future development of data mining in geosciences is likely the integration of data mining and physics modeling (Reichstein et al. 2019).

Data Visualization

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

As data has become abundant, data visualization has evolved as one of the most universally used data exploration and analytic methodology. There has been a recent uptake in availability of the open-source libraries and browser-based applications, leading to democratization of the use of visualization among data enthusiasts. Data visualization is formally defined as the visual representation of data based on specific mapping between visual constructs and aspects of data (Munzner 2014). Hence, visualization in itself is a multi-disciplinary pursuit involving design, data sciences, computer graphics, human-computer interaction, and required domain knowledge. From a geospatial or a geoscientific perspective, the commonly used terms for data visualization are geovisualization (MacEachren and Kraak 2001) and geovisual analytics (Andrienko et al. 2007). The goal of geovisualization has been to enable viewers or users to “explore, analyze, synthesize, and present” the data that defines the domain.

Overview

The usage of data visualization caters to a spectrum of requirements, spanning from data summarization to data

exploration. Each methodology has a combination of summarization and exploration goals in varying degrees. With the advent of high-throughput graphics processing units and interactive display technologies, most visualization systems or tools facilitate real-time rendering and effective human-in-the-loop workflows. Thus, what used to be infographics and static visualization have made way to dynamic visuals. The degree of interactivity in today’s graphical user interfaces varies from text pop-ups for mouse over to data transformations by slicing and dicing. Thus, data visualization and human-computer interaction have now evolved to be inseparable with respect to system requirements and subsequent implementation.

The graphical content of conventional visualizations in geosciences, just like another scientific domains, is determined by the data types. In geosciences, cartography has played a major role in visualization since the human quest for global exploration in maps. The use of cartography emphasizes the importance of visual embeddings, e.g., color schemes (Brewer 1994). The need for visual embeddings, mappings, or correspondences is as old as mankind, owing to its perceptual characterization. The cave paintings are lasting evidence of daily habits of the early Homo sapiens, which can be classified as spatiotemporal visualization, in today’s parlance. Spatiotemporal data is undeniably a key element in geoscientific understanding. Here, we first list out the types of visualizations one would encounter when looking for geosciences-related visualizations. We classify some of the commonly used visualizations into three broad types: (i) map-based visualizations using geo-referenced data, (ii) scientific visualizations using data with physical dimensions, and (iii) information visualizations using other kinds of data which exclude positional information, e.g., statistical measures or frequency data, categorical data, etc. These three types of visualization techniques are usually used in combination, e.g., in the form of overlays. A simple example would be a surface representing bathymetric data, with a map as a reference. The methods we discuss in this article also tend to have variants specific to the geoscientific subdomain where they are applied. For instance, marine geosciences require the use of ocean models and several multiscaled entities for data analysis including visualization (Xie et al. 2019). In that regard, Hovmöller plots or diagrams are unique to ocean data visualization.

Commonly used map-based visualizations include choropleth map, hotspot visualizations, network visualization, symbol map or glyph/icon-based visualizations, abstract visualizations such as cartograms, and three-dimensional projected visualizations. Choropleth map is a thematic map where regions in the cartographic map are colored based on a collective or aggregate value, e.g., population density in the USA, or a finer-grained one at the county level. In Fig. 1, we observe the seismic regions in India colored using a

Data Visualization, Fig. 1 Preliminary data of recent earthquakes in India in 2019, available in the form of a map-referenced point data visualization, rendered as glyphs. This website is an example of open

data dissemination by a governmental agency, e.g., National Center for Seismology, Government of India. Image courtesy: https://seismo.gov.in/MIS/riseq/earthquake/recent_earthquake

qualitative color scheme of blue-yellow-orange-red corresponding to Zones II-III-IV-V, respectively, indicating the increase in damage risk in the zones. Hotspot visualizations are similar to choropleth map in appearance, but the input to the visualization is point data as opposed areal data. From the point data, the kernel density estimation is done to identify regions of varying density from the hotspots, or highly dense clusters of points. Hotspot visualizations are used in the case of studying disease outbreak, traffic congestion, earthquake propagation, etc. Network visualizations include node-link diagrams to demonstrate connections and relationships. Ship trajectories, as shown in Fig. 2, is a good example. The node-link diagrams suffer from visual clutter caused by several crossing edges of the network. A way to minimize the clutter is to use curved edges and/or transparency in rendering the edges, as shown in Fig. 2. Edge bundling also helps in reducing visual clutter by emphasizing the density and directionality of edges.

Glyph-based visualization uses icons or glyphs, such as circles, to indicate points (Fig. 1), Chernoff faces for population value, etc., at specific points on the map. The glyph-based visualizations facilitate the use of glyph properties, such as its shape, size, and color, as visual marks for mapping point-wise variables. For instance, in Fig. 1, the size of the circular glyphs indicates the strength of the earthquake, the color,

and its depth in km. The abstract visualizations include cartograms, which are distorted shapefiles used in maps. These distortions are an outcome of constraining the shape and area of the shapefiles to meet specific criteria, e.g., area proportional to the value of a variable, or a frequency count for the variable. A cartogram is generated from the choropleth map. Contiguous, noncontiguous, and Dorling-type cartograms are generally used. Three-dimensional projections involve mapping onto surfaces of three-dimensional objects, such as sphere or cylinder. Thus, the three-dimensional map-based visualizations are essentially 2.5-dimensional ones of the globe and its variables. Google Earth is an example of such three-dimensional projections.

The scientific visualization techniques are used on two-, three-, and four-dimensional datasets, including varying combinations of three spatial and one temporal dimensions. Three common techniques for two-dimensional data are: (i) feature lines, e.g., streamlines and contours, (ii) colormaps, e.g., gradient colormaps and contour fills, and (iii) glyph visualization, such as arrow plot for air current visualization.

Contours or isolines have different names depending on what variable they represent, e.g., elevation contours for height, isobaths for ocean depth, isochrones for time needed to travel, isotherms for temperature, isobars for (atmospheric) pressure, and so on. An isoline for a specific variable and a

Data Visualization, Fig. 2 Data of worldwide ship routes in 2012, curated, archived, and represented as a map-referenced network visualization, rendered as node-link diagram, colored by ship type. This

website is an example of a publicly available exploration tool for archived data. Image courtesy: <https://www.shipmap.org/>

specific value is defined as the locus of points where the variable has the value, and the points are joined together piecewise by line segments. Isolines are used to partition space based on the variable value. As an example, an elevation line for a certain height, h , divides a two-dimensional surface data to a region with height greater than h , and otherwise. Apart from isolines, the feature lines also include vector field lines, such as streamlines, streaklines, pathlines, and timelines, used in vector fields, e.g., ocean currents. Streamlines are widely used vector field lines to understand “flow” orientation, as the vector direction at each point on the line is tangential to the field line. As an extension to three-dimensional volumetric datasets, these feature lines are to surfaces, such as isosurfaces, and visualized as colored or semitransparent surfaces. Figure 4 demonstrates surface constructed from bathymetric data and isosurfaces of salinity. Another technique used for volumetric visualization is direct volume rendering, which uses transparencies mapped to variable values to visually represent interfacial material boundaries. Direct volume rendering is a method which exploits the optical properties of the materials in the volume to enable a see-through visualization into the volume. This type of rendering works the best for data with layers of material, e.g., geological data, as in the simulation in Fig. 3.

Colormapping is the use of a color palette to map a color to a variable using interpolation functions, and subsequently

using the appropriate color fill for rendering surfaces. This is commonly used for continuous physical variables, such as temperature, pressure, particle concentration, etc. If intervals are used instead of interpolated functions, we get contour fills when using the color maps. Figure 3 shows contour fills of soil types in a simulated volumetric space. Interestingly, determining the appropriate gradient color palette for colormaps and qualitative color schemes for contour fills requires understanding of color perception and visual mapping (Brewer 1994).

The glyph-based visualization is the same as has been explained for map-based visualizations, and the similar concept can be used for continuous fields. A well-known example of glyphs is the use of arrows for vectors for encoding the magnitude, direction, and orientation of the vector at each point. Glyph-based visualization can also be extended to higher-dimensional space. Point cloud rendering of three-dimensional laser-scanned topographical data, as shown in Fig. 5, is considered to be a special case of glyph-based visualization.

The information visualization community categorizes map-based visualizations as abstract data visualizations. However, bearing in mind the presence of geo-referenced positional information in maps, we mention them separately here, in the context of geosciences. Without the abstraction of position, the design space of information visualizations is

Data Visualization, Fig. 3 Volumetric visualization of a simulation model of geology using a feature-rich browser-based graphical editor. This website is an example of a teaching tool for geology. Image courtesy: <https://app.visiblegeology.com>

Data Visualization, Fig. 4 (a) This is a combination of surface rendering of bathymetric data (brown) and contour extraction of salinity data rendered using the color spectrum in the legend, for salinity data on a slice at depth 800 m below sea surface in the Indian Ocean dataset. (b)

Isosurface of salinity, rendered in green, at 34.7995 PSU on 15 January 2004, in the volumetric data from the MOM4 ocean model of the Indian Ocean. Image source: Author's own; data source: <https://las.incois.gov.in/las/UI.vm>

large. This design space includes all the commonly used visualizations, such as statistical plots, fractals, diagrams, etc. We direct the reader to the recent handbook of mathematical geosciences (Sagar et al. 2018) for finding several examples of such visualizations. Apart from these, there are commonly used multivariate visualization techniques such as parallel coordinates plots, scatter plot matrices, matrix visualizations, etc., and hierarchical data visualization such

as treemaps, dendrograms, sun burst, etc., which are useful for understanding relationships between data entities.

The presence of time in the data gives rise to different kinds of visualization depending on its role as a dimension versus a variable. When time is a dimension, animation is the best method which mimics the passage of time. A good example of map animation is the use of time-lapse to demonstrate the changes on the earth during 1984–2016, using the

Data Visualization, Fig. 5 (a) Point rendering of Aerial Laser Scanned (ALS) point clouds of topographic data from Vaihingen site, Germany, using data provided by ISPRS as benchmark data. The red points are linear features, delineating structures, e.g., building roofs, and

localizing objects, e.g., foliage, and gray are remaining points. (b) Corresponding orthoimage. Image source: Author's own; data source: <https://www2.isprs.org/commissions/comm2/wg4/benchmark/3d-semantic-labeling/>

Google Earth Engine. Scientific visualization of time series also conventionally uses animation as a more effective ways to understand temporal changes. In information visualization, line graphs have been commonly used for time-varying one-dimensional signals. When time duration is a variable, e.g., geologic age of rock layers, then it is visualized just as any other variable using colormap, glyphs, etc.

Geovisualization and Geovisual Analytics

The aforementioned visualizations are generally integrated to form visualization systems for complex multivariate geospatiotemporal data. Different kinds of data and model scenarios involved in scientific disciplines tend to be multifaceted (Kehrer and Hauser 2012). Heterogeneity in data requires multiple coordinated views for visualizing the multiple facets, and workflows which can flexibly fuse elements at different levels, e.g., data level, visualization level, etc., for making inferences. Consequently, automated geoscientific analytic systems have visualizations in the graphical user interfaces using a combination of different visualizations in composite views to provide holistic insights to the data. For instance, the system for automated geoscientific analyses (SAGA) open-source geographic information system (GIS) provides users several options for visualization of varied kinds of data for different applications, such as soil mapping, climatological studies, etc. (Conrad et al. 2015). Visualization systems have

gradually and steadily paved the way for visual analytics, a relatively new terminology used for visualization systems that implement the endless feedback loop in data science workflow with human in the loop. This feedback loop allows inferential analysis from data using hypotheses built as consequences of data science workflows which predominantly involves visualization. Geovisual analytics (Andrienko et al. 2007) pertains to data from geosciences. Geovisual analytics for spatial decision support has been the singular research agenda for the community. This agenda is different from other visual analytics-driven work based on three aspects, namely the complex spatiotemporal nature of the concerned data, multiple stakeholders, and tacit criteria and knowledge. A motivating example of geovisual analytics is in the use of visualizations for emergency response in a disaster-affected region, say landslides. Synchronized dashboards of interconnected data of weather, road network, hospital locations, rescue camps, etc. enable quick decision-making, planning, and implementation by administration. Such dashboards use design patterns of user interactivity, such as brushing, linking, slice and dice, etc., which are also useful for researchers to perform in-depth study of the situation.

The evolution of visualization systems is strongly tied to the change in technologies involved. With the widespread usage of information and communication technologies in the late 1990s and early 2000s, the habits of both expert and casual users in working with data have also changed. There are more browser-based visualizations catering to several

needs, today, than ever before. Government agencies use them for data dissemination for public awareness (Fig. 1), data providers allow users to explore archived data (Fig. 2), and education experts use them as learning aids (Fig. 3). Also, visualization has increasingly become a way of open data sharing (Figs. 4 and 5).

Challenges, Opportunities, and Future Scope

While there has been technical advancement, the challenges pertaining to visualization have also changed with the technologies involved. The geovisualization research community have identified three persistent challenges, i.e., challenges which are long standing, rather than being of high priority (Çöltekin et al. 2017). Firstly, data visualization requires understanding of the disciplines involved, such as scope of the domains, inter-domain dependencies, and interdisciplinary collaboration. While the first issue is agnostic of the application domain, the second issue of gaps in systematic understanding of human factors is unique to human-in-the-loop computing. The third issue lies in the lack of practical guidelines that matches the visualization types to task types, and design guides for effective and appropriate geovisualizations for the user, thus bringing back the focus to the geoscientific domain. The third issue is, thus, specific to the geosciences. These research challenges of appropriate visual designs of spatiotemporal data, effective data representation for human consumption, and efficient system/workflow integrations have dogged the community for two decades (MacEachren and Kraak 2001).

The aforementioned challenges pave way to opportunities, such as democratization of visualization, which means there are a slew of open-source resources for visualization tools, systems, and libraries, to cater to the needs of the geovisualization community. “Democratization” refers to the extension of accessibility of such tools to a larger audience, not limiting to the visualization experts. Democratization, by design, improves the usability of visualization systems by more stakeholders. The browser-based tools especially have an appeal for reaching a wider audience, thus popularizing the scientific discipline, without the weight of the need of mathematical or programming knowledge to build the visualizations. The pandemic of 2019–2020 caused by novel coronavirus saw the rise of the browser-based choropleth map visualizations for knowledge dissemination of the progression of the pandemic at different spatial scales, namely states, countries, continents, and the proportion of the population being affected worldwide. The rise of such geo-referenced visualizations is also tangibly attributed to the concerted efforts in data gathering, and availability of cloud computing facilities. These visualizations organically grew from the popular consumption of data from browser-based

map applications, e.g., Google Maps, and crowd-sourcing data platforms. In tandem, computing systems using the graphics processing unit (GPU) facilitating browser-based rendering using HTML, WebGL, and Python programming constructs have enabled the implementation.

The future of geovisualizations lie in using them in more complex usage scenarios, with a renewed focus on geoscientific education. Visualizations are consumed using augmented and virtual reality which can be used effectively, e.g., augmented reality sandbox kit for students to interactively build landscape and understand water flow modeling on such landscapes. Current visualizations also focus a lot on the raw data, and there is a large space for seamless integration of visualizations and data transformations. One of the immediate applications is in understanding uncertainty in the data itself, which needs to be studied further, given that “data is the new oil.”

Overall, data visualization is an analytic process which provides insights to data using human-computer interaction, in applications providing data summarization and data exploration in varying degrees. In this entry, we have introduced the topic of data visualization in the context of mathematical geosciences, described common visualization techniques, discussed about its current state in the context of usability and computations, and, finally, impressed on the challenges and opportunities for geovisual analytics practitioners.

Database Management System

Rajendra Mohan Panda¹ and B. S. Daya Sagar²

¹Geosystems Research Institute, Mississippi State University, Starkville, MS, USA

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

Data management is a process to acquire, store, process, and apply data effectively without compromising the safety and integrity of data use and distribution.

Terminology

An archive is a storage space to keep important information, documents, or objects.

Archiving is the process of data duplication to create new copies for Pen Drive, Hard Disk, other external storage, cloud servers like iCloud, Google Drive, OneDrive, etc.

Compression ratio is the ratio of uncompressed file size to the compressed file size

Data Analysis is the process of understanding data to derive useful information.

Data Archiving is a data backup process.

Data are a collection of facts or figures or information.

Metadata is the information about the data

Introduction

Data management started with punch cards. It came to the limelight with the establishment of the Association of Data Processing Service Organizations (ADPSO) in 1960 (SAS 2022). The data management systems were strictly operational. With the internet, digital data use exponentially increased and these voluminous data needed systematic monitoring in a fast and flexible way without compromising safety. This data monitoring process involves the acquirement, storage, processing, and applications effectively. It represents the overall control policies or protocols of an organization for the productive use of data with focuses on data integrity, governance, quality, and security and storage (USGS 2022). Different organizations have different policies to use and share data and hence, separate data management plans for wise use data. Overall, data management, which involves the collection, secure execution, and monitoring of

data, has a life cycle starting from its inception to final retirement including its progress and failures. Data management has several benefits in multiple applications:

- Strategic decision making
- Good governance
- Greater collaboration
- Increase visibility
- Marketing and networking
- Operation management
- Improving organizational agility
- Prioritizing privacy
- Safeguard piracy
- Secure use
- Sustainable development
- Organizational growth
- Systematic reporting
- Timely compliance

The best data management practices focus on:

- Metadata Management
- Data Quality
- Data Security
- Data Integration
- Data Governance
- Data Storage

Metadata Management

Metadata is information about data. It describes the form, structure, types, attributes, records, summaries, and other key features of data. Its management involves generating, filtering, and searching metadata, which helps us to understand data for better usability. Metadata management facilitates consistent data enhancement processes. Broadly, metadata management is classified into operational, technical, and business categories.

Quality

Data quality describes the correctness and consistency of data. It helps in identifying data deficiencies or completeness and availability. Data quality management assesses data correctness, consistency, integrity, and frequency of distribution. It includes the completeness, collection time, spatial extent, and background information. Completeness checks about the missing information and accuracy. The data collection details about time, extent, location, coordinates, background information, and any other specification that may be essential for proper data assessment. Data quality management has a significant role in better data integrity, quality checking, and also, its improvement.

Security

Data security deals with the protection of data use and release processes. Its management focuses on conditions of access, use, and sharing data. Data security management complies with the General Data Protection Regulations (GDPR). It includes access control, auditing, masking, and tokenization. *Access* is a secure login process with two- or three-factor authentication to access data with permissions. DUO authentication is a common practice in secure login, common practice in cloud computing. Auditing deals with record keeping and documentation to trace data on demand. Unique identifiers are assigned for data for easy auditing. Data security management has significant control over the deletion or substitution of data based on preset rules. It helps organizations streamline data use conveniently and effectively with protection.

Integration

Data integration is data consolidation from different sources into a single dataset providing users with consistent access and delivery of data across multiple spectrums to justify the information needs of all applications and stakeholders (Lenzerini 2002).

Governance

Data governance includes analysis, classification, and maintenance of data. It covers data structure, its use, and distribution. It is required for the smooth function of an organization. A well-defined data management system helps in the effective development of an organization.

Storage

Storage is a significant part of data management, which deals with frequent data export and backup of newly created or modified data files. Data compression is a common method to store more data using less space.

Data Compression

Compression reduces the storage space of files or folders by compression. A JPEG file can reduce a little as 80% and MP3 by 90%. But single file compression suffers the loss of data transparency, color, sound, etc. Alternately, folder compression reduces data storage space without the loss of a single bit. The data compression procedures for multiple files to a single file are called “archive” and formats used for storage space reduction are called “archive formats.”

Archive Formats

Several archive formats are used for data compression. The efficiency of different data archiving formats is measured using two terms: compression ratio and compression speed. Data compression ratio is the relative reduction in data size by

applying a compression algorithm, expressed as a ratio of uncompressed size to compressed size:

$$\text{Compression ratio} = \frac{\text{Uncompressed data size}}{\text{Compressed data size}}$$

$$\text{And, \% space savings} = \left(1 - \frac{\text{Compressed data size}}{\text{Uncompressed data size}}\right) \times 100$$

$$= 1 - \frac{\text{Number of bits after compression}}{\text{Number of bits before compression}}$$

During compression and decompression, some memory is always consumed, which after completing regains the memory (IBM 2022). The speed is a simple ratio of energy bits before or after compression to time (s):

$$\text{Compression speed} = \frac{\text{Compressed bits}}{\text{Compression time}}$$

$$\text{Decompression speed} = \frac{\text{Decompressed bits}}{\text{Decompression time}}$$

The major formats include Zicxac Inline Pin (ZIP), Roshal Archive (RAR), Tape Archive (TAR), GZIP, and 7Z. ZIP is the most commonly used archive format with the highest compression speed and minimum compression ratio compatibility with Windows and Linux systems. ZIP uses DEFLATE for data compression, and WinZip, WinRAR, and 7-Zip for extraction. It stores and extracts files separately. RAR is another popular data compression method, compatible with Windows and macOS. It can compress files by using the WinRAR application but extraction is possible both by WinRAR and WinZip. It has a better compression feature than ZIP. 7Z has the highest compression ratio and minimum compression speed. It is compatible with Windows, Linux, and macOS. It supports multiple applications for compression (LZMA, PPMD, BCJ, Bzip2, Deflate), extraction (7-ZIP), and encryption (AES-256). Its program and file formats are available for free. TAR.BZ2 and TAR.GZ also have open standard licenses like 7Z. TAR.BZ2 is not better than 7Z although its compression rate and speed are better than ZIP and TAR.GZ. BZIP2 and GZIP applications are used to compress TAR archive files to TAR.BZ2 and TAR.GZ. TAR.BZ2 has an intermediate compression speed and compression ratio. TAR.GZ has the highest compression speed and low compression rate. Both support storage of files in Windows, Linux, macOS. It uses GZIP to compress files, but with high compression speed and compression ratio.

Storage Devices

Storage devices are used for data backup or recovery. Magnetic tapes or disks, CDs, DVDs, and Universal Serial Bus (USB) are used for such backup and storage. USB is now common for its higher bandwidth and power supply capability. External hard drives and other drives of the same computer are often used to copy data.

Backup Types

System backup or file backup are two major backup types. The system backup stores everything including operating system and applications, whereas file backup keeps copies of files. The file backup includes differential or full backup and incremental or delta backup. As the name suggests, differential backup copies selected files, unlike full file backup. The incremental file backup appends the selected files without replacing the previous files, but delta backup stores the change portion of the data. The automatic storage of data is often required to transfer data from one storage medium to another based on some predetermined criteria: age, category, etc. Solid State Drives (SSDs) are popular devices for such storage activities. It is preferred to hard disks for having better holding capability to the frequently used datasets, high storage speed, greater reliability.

Cloud Storage

Cloud computing is a recent phenomenon in the internet world. It is a replacement for in-house operations offering service online. It started as a software service for providing online data management in a user-specific computer. Cloud servers are capable of managing huge data traffic with provisions for expansion and contraction. Several service providers: Amazon (Amazon Drive, Flickr), Google (Chromebook, Google Drive, Google Docs, G Suite, Google I, Google Photos), Microsoft (Azure, OneDrive), Dropbox (Dropbox), IBM (IBM Cloud), and Apple (iCloud, iCloud Drive) have revolutionized these online applications replacing large dependencies of in-house data management. These remote internet services for data storage, processing, and management combined with the infrastructure arrangements are *cloud computing*.

Cloud computing uses artificial intelligence (AI) and machine learning to automate multiple data management tasks simultaneously. It offers benefits for data backups, security, and governance such as

- Complexity reduction
- Accuracy improvement
- Increased reliability
- Secured use
- Operational efficacy
- Reduced operational cost
- High-performance

Big Data Management

Big data management is complex and involves more sophisticated technology for smooth and automated acquisition,

storage, transfer, and usage. Lyko et al. (2016) have described the following steps for big data management:

Data acquisition $\Rightarrow$ Data Analytics $\Rightarrow$ Data Curation $\Rightarrow$ Data Storage $\Rightarrow$ Data Usage

Data can be structured or unstructured, simulated or satellite based. These data are systematically verified by analytical approaches: machine learning, stream mining, and semantic analyses. Data analytics involves ecosystem, community, cross-sectoral, or global analyses. Data curation is one of the most significant steps in big data management. It includes data quality, data accuracy, automation, and interpretability. The next important step is data storage, which takes care of performance, security, consistency, and availability. The access and availability are determined by certain standardized protocols designed by each organization. Finally, data helps in wise decision making, predictions, simulations, explorations, and visualization, etc. Cloud computing is believed to be the best available solution for big data management.

Remote Sensing Data Management

Remote sensing data are huge and their acquisition, processing, storage, analysis, and visualization are critical for monitoring soil properties and crop production. Its management is significant for decision support in fertilization, irrigation, and pest control (Huang et al. 2018). The significance of certain bands of electromagnetic spectrum, e.g., infrared and microwave in vegetation and soil moisture (Moran et al. 1997; Mulla 2013) and to other features necessarily demands systematic handling of big data. This involves storage, processing, extraction, and visualization in a time-specific, fast, and realistic manner, essential for precision agriculture.

In general, remote sensing data acquired from different satellites or other sources (e.g., aircraft, drones) have noise. These noises appear due to interactions between the atmosphere, terrain features, and sensors. These errors are corrected before further data processing. Sometimes these data are resampled or rescaled to make some adjustments to the requirements. Image fusion is often needed to create a common coverage for images from multiple sources and scales or resolutions. The fusion that enhances image quality is commonly applied at a pixel level. The images are classified applying various algorithms such as maximum likelihood, machine learning, and object-based classification (Walter 2004; Huang et al. 2018). Deep learning has also been applied to remote sensing data classification (Mohanty et al. 2016).

Classified images are visualized by using the GIS platform, which has immense capabilities of voluminous data, collaboration, integration, and systematic application. However, problems of data integration, validation, and accuracy assessment need further research for complex remote sensing data management.

Conclusions

Data management is critical for organizations to find data reliability and its optimal use. It is a standard process essential for understanding data for good governance and meaningful decision making. It becomes more complex with big data acquisition. Its curation, storage, and usage need systematic management practices to achieve trusted data acquisition, distribution, and automation. The Internet revolution has solved these problems of big data management by replacing in-house operations. Cloud computing is the recent phenomenon that allows third-party management of these huge data resources. Remote sensing data management is complex with issues related to accuracy, validation, and integration. Machine learning and deep learning algorithms in GIS platforms are continuously adding new features. The technology development for error minimization and improvements in future data management is not so far.

David, Michel

Denis Marcotte

Department of Civil, Geological and Mining Engineering,
Polytechnique Montreal, Montreal, QC, Canada

Fig. 1 Michel David (right) accepts Krumbein Medal from IAMG President John Davis (Source: JAMG Newsletter 38)

Biography

Michel David was born in France in 1945 and received his first degree in 1967 as *Ingénieur civil des mines* from *Université Lorraine* in Nancy. Trained in geostatistics by George Matheron, Michel David obtained his Ph.D. at Montreal University (1973) in the department of computer sciences and operational research. He was professor of geostatistics (1970–1987) in the mineral engineering department at Polytechnique Montreal, the first university in the Americas to include a geostatistical course in a regular curriculum. He was coorganizer and coeditor of the first two International Geostatistical Congresses in Frascati, Italy, in 1975 and Lake Tahoe, Nevada, in 1983.

Despite the relative brevity of his academic career, he is recognized as one of the key actors for the initial spreading of geostatistical methods among practitioners of the mining industry. In particular, Michel David wrote the first English language textbook on geostatistics applied to mining problems, *Geostatistical Ore Reserve Estimation* (David 1977). A second book, *Handbook of Applied Advanced*

Geostatistical Ore Reserve Estimation, was published in 1988. He was a leader in international geostatistical consulting for mining companies. Furthermore, he became director (1976–1981) of the *Mineral Exploration Research Institute*, and he founded *Geostat Systems International*, a geostatistical consulting company having antennas in Denver (1979) and Montreal (1981). Michel David was proud of defining himself as a teacher, etymologically “a person who shows.” Hence, in addition to his regular courses, this love for teaching lead him to give numerous short courses on geostatistics reaching over a thousand mining professionals around the world.

Michel David’s research was applied to and mainly rooted in typical mining problems. Illustrative examples are the statistical ore dilution problem (the “vanishing tons”) due to support effect and smoothing effect, and the importance of conditional bias encountered with many estimation methods. He was sensitive to the importance of communicating simply the implications, for mining practice, of abstract geostatistical concepts. He also proposed useful empirical tools for practitioners, such as the relative variogram (general and pairwise) and the lognormal shortcut method for estimation of local recoverable reserves. Among other subjects worth mentioning that attracted his attention are the automatic mapping with intrinsic random functions of order k and various geological applications of multivariate classification and of correspondence analysis, a factorial method particularly well suited for the analysis of ubiquitous composition data in geology.

Michel David died in 2000. The importance of his role and contribution to geostatistics and resource evaluation was recognized by the attribution, in 1987, of the W.C. Krumbein medal of the International Association for Mathematical Geology and by his nomination as Fellow of the Academy of Science of the Royal Society of Canada in 1988. Moreover, an international Forum was held in his honor in 1993 in Montreal and a special issue of *Mathematical Geology* was devoted to Michel David in 2005 as a tribute to his legacy.

Davis, John Clements

Ricardo A. Olea

Geology, Energy and Minerals Science Center,
U.S. Geological Survey, Reston, VA, USA

Fig. 1 John Clements Davis. (Courtesy of Jo Anne Degraffenreid)

Biography

John Davis was among those who first used computers to address geological problems, thus helping to transform geology from a purely descriptive to a more quantitative science. His early work on computer mapping and application of multivariate statistics to geological data led to Davis’s most influential publication, his textbook *Statistics and Data Analysis in Geology* describing these and other quantitative methodologies. The book was widely accepted and was revised through three editions paralleling the evolution of information technology. The first edition (Davis 1973) included simple FORTRAN routines for methods discussed in the book. Enhanced versions came on a diskette in the 1986 second edition, for the third edition in 2002 files could be downloaded over the Internet. Davis was also active in the probabilistic assessment of petroleum prospects and evaluation of geologic hazards, and authored over 100 papers.

John joined the Kansas Geological Survey (KGS) in 1967 and remained there through 2003. As Head of the Mathematical Geology Section he had a lasting influence locally and worldwide. He maintained a “Visiting Scientist” position that allowed his group to host for one or two years some of the most renowned specialists in geomathematics and computer applications, including several of the biographees in this encyclopedia. This cooperation was critical in the development and testing of many techniques that today are routinely used in the earth sciences. Davis also served as professor of petroleum engineering at the University of Kansas and later at the Montanuniversität in Austria, teaching several generations of young geologists and engineers.

John Davis was born in Neodesha, Kansas, on 21 October 1938. He graduated from the University of Kansas with a BS in geology, then moved to the University of Wyoming as an

NDEA Fellow, earning an MS in 1963 and a PhD in 1967, both in geology. John was generous with his time and talents by being active in several professional organizations. He served on several early committees promoting computer applications to geology and taught industry short courses for the American Association of Petroleum Geologists (AAPG). John was Western Treasurer of the International Association for Mathematical Geosciences (IAMG) for 8 years, then was elected secretary-general in 1980, and served as president from 1984–1989. The IAMG presented Davis with the Krumbein Medal in 1986 and the Geological Survey of Austria bestowed on him the Wilhelm Ritter von Haidinger Medal in 1999, both for outstanding contributions to the profession.

De Wijs Model

Shuyun Xie

State Key Laboratory of Geological Processes and Mineral Resources (GPMR), Faculty of Earth Sciences, China University of Geosciences, Wuhan, China

Definition

De Wijs model is a typical multifractal model, which was introduced by De Wijs (1951, 1953) to study the spatial distribution, redistribution, or enrichment/depletion patterns of elements based on multiplicative cascade processes, and has now been widely applied in different fields and especially played a pivotal role in modern geostatistics (Diggle et al. 2010; Mondal 2015).

Introduction

In the early 1950s, H. J. De Wijs (De Wijs 1951, 1953) discovered a well-known distribution model in studying the element distribution of minerals in rocks, which was later called De Wijs model. The self-similarity criterion contained in the model makes it considered as a fractal model (Mandelbrot 1975), more precisely, a typical multifractal model (Evertsz and Mandelbrot 1992). The data published

by De Wijs (1951) is also called De Wijs data, which has been regarded as the classical fractal data set in Geostatistics. Since 1960s, De Wijs model and data have been widely and deeply studied (Krige 1952, 1958; Agterberg, 1974, 1981, 2005, 2007, 2012; Xie and Bao 2004). Matheron (1962) proved that De Wijs model data would produce logarithmic variogram. The data set is proved to obey multifractal distribution, and the multifractal variation function model in theory is proposed based on the De Wijs data (Cheng and Agterberg 1996). Cheng (2000, 2015a) first studied the local singularity analysis and multifractal properties of De Wijs data.

De Wijs model and data has also been used to test the efficiency of various multifractal methods before dealing with different geochemical data sets (Chen et al. 2007; Gao, 2010; Cheng 2015a). Using the binomial De Wijs model (1951) as an example, the issues of microcanonical versus canonical conservation, algebraic (“Pareto”) versus long tailed (e.g., lognormal) distributions, multifractal universality, conservative and non-conservative multifractal processes, and codimension versus dimension formalisms were discussed deeply (Lovejoy and Schertzer 2007). The relatively simple one-dimensional De Wijs multiplicative cascade model has also been used to discuss the lacunarity for fractals, multifractals, and some nonfractals, introduce the relation between multiplicative cascade processes and information integration processes, and demonstrate the formation of fractal density (Cheng 1997, 2012, 2015b). The De Wijs scheme has also been followed to analyze mineral production data and to simulate the distribution of deposits and for mineral resource appraisal (Ford and Blenkinsop 2009; Gumiel et al. 2010; Arias et al. 2011; Agterberg 2018).

De Wijs Data

Analytical assay data for 118 Zn contents from a sphalerite-quartz vein near Pulacayo in Bolivia, as shown in Table 1 (De Wijs 1951), were published. These 118 channel samples were cut every 2 m in a 240-m-long vein crossing horizontal block of sphalerite-quartz veins (446 m underground). The massive veins were only 0.5 m wide on average and contained disseminated sphalerites in the surrounding rocks on both sides (Agterberg 1974; Chen et al. 2007). These channel samples provided unbiased estimates of zinc concentrations in 2-m-long blocks analyzed along the vein direction. Thus, the 118 geochemical data of Zn contents represent a standard data set which was measured from the samples collected at standard equidistant distances. Although the number of sampling points is very small, as a first example of an in situ horizontal analysis in ore-forming areas, the famous zinc concentration assay values (de Wijs 1951) have been studied by scholars many times and also reanalyzed again and again (Lovejoy and Schertzer 2007).

Figure 1 shows the statistical distribution plots of De Wijs Data set as shown in Table 1. Figure 1(a) is the Zn content (%) of 118 Samples, and Figure 1(b) shows the value of natural

De Wijs Model,

Fig. 1 Distribution of De Wijs Data set (a) Zn content (%) of 118 Samples; (b) Value of natural logarithm of Zn content; (c) Histogram of Zn content; (d) Histogram of natural logarithm of Zn content; (e) Q-Q plot of Zn content; (f) Q-Q plot of natural logarithm of Zn content; (g) Boxplot diagram of Zn content; and (h) boxplot diagram of natural logarithm of Zn content

logarithm of Zn content. Correspondingly, Figure 1(c) is the Histogram of Zn content; Figure 1(d) is the Histogram of natural logarithm of Zn content; Figure 1(e) is Q-Q plot of Zn content; Figure 1(f) is Q-Q plot of natural logarithm of Zn content; Figure 1(g) is Boxplot diagram of Zn content; Figure 1(h) is boxplot diagram of natural logarithm of Zn content. Obviously, De Wijs showed that the 118 zinc values were approximately log-normally distributed as shown in Figure 1.

Figure 2 is the multifractal spectrum curve of Zn content distribution which is calculated by the method of moments (Halsey et al. 1986; Evertsz and Mandelbrot 1992). It can be seen clearly that the data set is of continuous multifractal property (Cheng and Agterberg 1996).

Selected Case Study of De Wijs Model

De Wijs model describes the iterative segmentation process of metal element distribution of self-similarity. Assuming that the ore vein with volume V initially has average grade Z_v , it is divided into two blocks on average, with grade values of $(1 + d) Z_v$ and $(1 - d) Z_v$ respectively; $0 \leq d \leq 1$. d , also called dispersion index, is the basic constant of the model,

which has nothing to do with the size of block V . Therefore, the metal content is relatively enriched in one subarea and relatively depleted in the other. After repeating the above two operations for n times, the block volume V is continuously cut out, and the relative enrichment or depletion degree of the metal content in it becomes higher and higher, and the overall distribution of grade becomes extremely uneven. Theoretically, it obeys the logbinomial distribution, and their logarithms have dispersion variance (De Wijs 1951; cf. Matheron 1962, p. 309). The construction of De Wijs model depends on three parameters: the overall average concentration Z_v , the dispersion index d , and the number of segmentation n . The relationship between the extreme value of multifractal singularity index $\alpha_{\min}$ and the parameter d of de Wijs model is proved (Agterberg 2001). The multifractal characteristics of the De Wijs model are studied, and the degree of enrichment d is identified by one multifractal detrending moving average analysis (MFDMA) method (Lai and Wan 2016).

For the De Wijs model in two-dimensional space, the multifractal patterns based on De Wijs multiplicative cascade models can be constructed as follows. Without loss of generality, the initial concentration Z_v is set as 1 in one region. Then the region can be divided horizontally into left and right

De Wijs Model,**Fig. 2** Multifractal spectrum
Curve of Zn content distribution
from De Wijs data**De Wijs Model, Fig. 3** Modeling De Wijs data with or without local superimposition of different dispersion indexes. (a) Data 01: $d = 0.2$; (b) Data 02: $d_1 = 0.2, d_2 = 0.6$

subregions first, then the two subregions are further vertically divided up and down, and thus the subregions are continuously divided into four parts, and the increasingly uneven singularity distribution in the whole space can be obtained. Keeping the dispersion index d constant, the concentration values are now $(1 + d)^2$, $(1 + d)(1 - d)$, $(1 - d)(1 + d)$, and $(1 - d)^2$ after first iteration. According to this iterative rule, the four small subregions can still be divided into four smaller regions. This process can be repeated indefinitely, but in fact, after only a few rounds, the data is dense enough for us to study the spatial distribution patterns of geochemical data. Figure 3(a) is the result of simulated data after five iterations when we choose the dispersion index d of 0.2. Figure 4(a) is the multifractal analysis results of De Wijs modeling data when $d = 0.2$. It can be seen that such kind of construction results based on De Wijs modeling are of typical symmetrical multifractal spectrum curve.

**De Wijs Model, Fig. 4** Multifractal analysis results of De Wijs modeling data with or without local superimposition of different dispersion indexes. (a) Data 01: $d = 0.2$; (b) Data 02: $d_1 = 0.2, d_2 = 0.6$

De Wijs model is also used to simulate the geological process of superimposition of late stages. In the long history

of geological evolution, such as in the process of mineralization, materials are often considered to have different stages of local superposition. A current geochemical field is the final product of a series of geological and geochemical processes in a specific area. In each process, ore-forming materials from different sources may be added to form geochemical anomalies in the geochemical background. In order to simulate this process, De Wijs data set based on the dispersion index d_1 of 0.2 is considered as a typical background field, and the simulation results are locally superimposed on the upper left corner of the model by another De Wijs data set with the dispersion index d_2 of 0.6. The overlay area is arranged in $1/16$ or 32×32 grids of the total area. Figure 2 and Figure 4(b) show the De Wijs dataset and multifractal spectrum curve with local superposition effect, respectively. Obviously, in Figure 2, the later superimposition implies more obvious local singularity and is easier to form strong geochemical anomalies. Figure 4(b) shows that the original multifractal spectrum curve becomes asymmetric and presents a left deviation pattern due to the superposition of late processes, which is considered to be a favorable metallogenic mode (Xie and Bao 2004).

Some new methods have been proposed to make the De Wijs model more universally applied. For example, the generator matrix of De Wijs model is set as a nonsquare matrix, so that self-affine multifractal distribution patterns can be generated. In addition, before each segmentation, the positions of each element in the generator matrix are randomly changed or changed with some constraint conditions, so as to generate random multifractal distribution patterns (Agterberg 2007). By changing the parameter d in the model construction, De Wijs model is also derived from the random variables to generate isotropic geochemical data and anisotropic geochemical data of different spatial distribution patterns (Chen et al. 2007).

Summary and Conclusions

Such kind of data construction process of De Wijs model is one of typical multiplicative cascade processes which captures the basic features of the forming processes of geochemical fields through many rounds of material redistribution, enriched somewhere and depleted elsewhere. And hence, it has been used as a conceptual but idealized model to simulate the multifractal geochemical fields with both isotropic and anisotropic backgrounds and anomalies, which played a vital role in modern geostatistics and mathematical geosciences area.

²Systems Science and Informatics Unit, Indian Statistical Institute, Bangalore, Karnataka, India

Definition

A decision tree is “a regression through classification for data mining and other applications represented with an inverted tree-like structure, where the root at the top is the input and leaves at the bottom are the outcomes or decisions.”

Terminology

Root node: Input for the decision tree splits into internal nodes which ultimately terminate as a decision node. The root node is the parent node of internal nodes.

Internal node: Intermediate nodes (or branches) are child nodes of the root node. Internal nodes split into decision nodes and are parent nodes of decision nodes.

Terminal node: Decision nodes (or leaves) are child nodes of internal nodes. Decision nodes do not split and have no child nodes.

Depth: Number of splits or divisions.

Pruning: Selective removal of internal nodes or sub-nodes.

Splitting: Division of data to nodes or sub-nodes.

Introduction

A decision tree is a machine learning technique for decision-based analysis and interpretation in business, computer science, civil engineering, and ecology (Bel et al. 2009; Debeljak and Džeroski 2011; Krzywinski and Altman 2017). It provides solutions to varieties of regression data mining problems used for decision making and good management practices (Maimon and Rokach 2005; Breiman et al. 2017). A decision tree derives the conclusion of an event through a series of regression and classification. The input for a decision tree is the best predictor and is defined as the root node. The root node splits recursively into decision nodes in the form of branches or leaves based on some user-defined or automatic learning procedures. In principle, a decision tree is a regression through inductive classification. Inductive classification is a computational procedure to extract the relevant information from unknown data through repeated splitting. A decision tree is a common tool for decision making and has many procedural advantages such as (a) simple data preparation, (b) easy interpretation, (c) less vulnerability to outliers, (d) capable of fitting both categorical and numerical variables, and (e) effectiveness in nonlinear setups. A decision tree needs less computational power for model building and low memory catch-ups. Despite several advantages, a decision tree cannot apply to continuous variables of infinite sizes (Rutkowski et al. 2014). The decision tree is often unstable and error-prone. These instabilities in the decision tree are taken care of by bagging and boosting (discussed later).

The decision tree algorithms differ mainly in their formation, e.g., (a) binary or nonbinary and (b) measure of impurity or uncertainty (Rutkowski et al. 2014). Several decision tree algorithms e.g., ASSISTANT, CART (Classification and Regression Tree), C4.5, chi-squared automatic interaction detection (CHAID), ID3 (Iterative Dichotomizer 3), and quick unbiased efficient statistical tree (QUEST), are proposed and some of the most popular methods are discussed. They include ID3 (Quinlan 1986), its extended version C4.5 (Quinlan 1986), and CART (Breiman et al. 1984). ID3 measures the entropy (a measure of uncertainty or randomness), where data split iteratively into many subsets until they belong to the same class. The entropy is calculated using the following formula (where ‘ p ’ is the probability of target class

'i' and 'c' is the number of observations/outcomes/possibilities):

$$\text{Entropy} = - \sum_{i=1}^c p_i * \log_2(p_i)$$

In the advanced version of ID3 (C4.5), the data splitting was based on information gain (difference in entropy values between parent and child nodes), where the data splitting is done by checking the decrease in error rate. Greater weight is given to attributes with large domains and the final class is decided by a majority vote. C4.5 algorithm is based on the gain ratio that selects the best one out of all possible splits. The gain ratio is defined as:

$$\text{Gain ratio} = \frac{\text{Information gain}}{\text{Entropy}}$$

where Information gain = Entropy_{parent node} – Entropy_{child node}.

But this version of C4.5 has the disadvantage of giving importance to rare classes disproportionately. Lewis and Catlett (1994) corrected these discrepancies in C4.5 by the probability threshold of the loss ratio (LR / LR + 1), but not by the majority vote (Lewis and Catlett 1994), where the loss ratio (LR) is a relative cost of false positives or false negatives. The LR = 1 gives equal importance to both errors, the LR > 1 gives more value to the false positive than the false negative, and alternately, an LR < 1 prioritizes false negatives on false positives. The probability threshold of the loss ratio assigns the class values at the decision node by specifying the false positives and false negatives through sensitivity analysis and the maximum normalized information gain.

The CART algorithm is a binary tree based on Gini's impurity index (Breiman et al. 1984). The Gini index measures the deviations between the probability distributions of each split and selects a sample with a minimum loss function. A Gini index value at zero indicates perfect purity and a value at 1 describes the maximum impurity. The Gini index is defined as:

$$\text{Gini Index} = 1 - \sum_{i=1}^c (p_i)^2$$

where 'p' is the probability of target class 'i' and 'c' is the number of observations/outcomes/possibilities.

Based on the type of tree produced, ID3 and C4.5 are nonbinary and CART is binary. ID3 is the fastest and only applicable to categorical variables, whereas C4.5 and CART are efficient in dealing with categorical and numerical algorithms. While ID3 cannot handle missing values, C4.5 and CART can easily handle missing values. On the other hand, CART has an efficient mechanism to eliminate nonsignificant variables, but not C4.5. While the calculation of entropy is slow, the Gini index is faster. Although all three popular

learning mechanisms have some advantages and disadvantages, CART is considered to be simple but most useful in recent research (Krzywinski and Altman 2017).

Stability in a Decision Tree

Decision trees group observations of similar response values, but a small change in observed values or data sample has the propensity to create perturbations in extracting information. These discrepancies in information extraction affect the predictability of a decision tree, and an unusual result might occur without realistic conclusions. To check these instabilities in the predictive performances of a decision tree, many algorithms are used. Bootstrapped aggregation (bagging), boosting or arcing (adaptive resampling and combining), and pruning adjacent nodes of low gain are widely used methods for the maintenance of such stabilities and overfitting (Maimon and Rokach 2005). *Bagging* helps in decreasing the variance in the prediction by generating multiple datasets for training through randomization and repetitive combinations. *Random forest*, a popular model for predictive analysis, is based on the principle of bagging. This ensemble method increases variance in the tree through random subsampling and reduces attributes available at leaf nodes for tree formation to a minimum. On the other hand, *boosting* adjusts the weight of an observation based on the best iterative class. Boosting generates multiple sets of training variants and fixes the classification errors by paying greater attention to the variant classified incorrectly. Boosting has wide applications in popular predictive models such as *gradient boosting models* and *support vector machines*. Both bagging and boosting are weak learners, but when combined, both create a strong learner. The deeper the decision tree, the more complex the model. There are numerous software tools for decision tree analyses and these are categorized based on operational compatibilities, computational speed, abilities in data handling, algorithm structure, and usability (Table 1). Software tools use datasets in .txt and/or .csv file formats for decision tree analysis. The output specifications vary with the tools.

Practical Implications of Decision Tree Analysis

The Eastern Himalayas Example

The decision tree analysis was applied to investigate the influences of major climatic predictors on the plant richness (number of species) in the Eastern Himalayas (Panda 2018). The tree described the greater influence of potential evapotranspiration (PET) on plant richness at >1163 ha/yr. Within this limit, an increase in temperature seasonality (>476.8) could further enhance plant richness. A low level of

precipitation seasonality (≤ 82) could further increase plant richness, but with a decrease in temperature seasonality (≤ 6.8). On the other hand, plant richness was found to decrease substantially with the decrease in potential

evapotranspiration ≤ 899 ha/yr. The precipitation seasonality was a crucial factor for plant richness at > 109 mm (Fig. 1a). Similarly, mean annual precipitation (PAN, > 1719 mm) led to an increase in plant richness subject to high-temperature

Decision Tree, Table 1 Popular software tools/libraries for decision tree analysis

Software tools	Windows	Linux	Mac	Libraries	Remarks
KNIME	√	√	√	N/A	Powerful and popular with 1500 modules and a wide choice of advanced algorithms
MALLET (Machine Learning Language Toolkit)	√	N/A	N/A	Java	Efficient to convert text to features, with applications in Maximum Entropy, and Naïve Bayes
OC1 (Oblique Classifier 1)	√	√	√	ANSI C	AI and graphical display in astronomy and forensic sciences with options for standard and oblique (multivariate) trees
Orange	√	√	√	Python	Worldwide applications in teaching and training institutes, with support for Tree Learner, Simple Tree Learner, and C45Learner
Rapid Miner	√	√	√	Java	No prior coding knowledge required Easily integrate with Weka
Rattle	√	√	√	R	Applications in statistics, business, teaching, and training
Scikit-learn	√	√	√	Python	Support for ID3, C4.5, C5.0, CART algorithms
SilverDecisions	√	√	√	Java	Software to create decision trees in research and development; image export options for 'json', 'png', and 'svg' formats
Simple Decision Tree	√	√	√	N/A	Excel Add-in
SMILES	√	√	×	C++	Compatible with ensemble models and neural networks
Weka (Waikato Environment for Knowledge Analysis)	√	√	√	Java	Powerful tool with support for ID3, C4.5, Naïve Bayes, k-nearest neighbors
YaDT (Yet another Decision Tree builder)	N/A	N/A	N/A	C++	Support C4.5 algorithm

Decision Tree, Fig. 1a Interactions between precipitation seasonality (PS), potential evapotranspiration (PET), and temperature seasonality (TS) and plant richness; 'n' describes strengths of each node

Decision Tree, Fig. 1b Interactions between precipitation seasonality (PS), annual precipitation (PAN), and temperature seasonality (TS) and plant richness; 'n' describes strengths of each node

seasonality (i.e., >463.6). The temperature seasonality of ≤ 463.6 and precipitation seasonality of ≤ 82 accelerated plant richness of the Eastern Himalayas. Alternately, a heavy mean annual precipitation (i.e., >2983 mm) could decrease plant richness by water-logging and probably due to seed rotting. The precipitation seasonality of >93 could reduce the plant richness further, even at a low level of temperature seasonality, i.e., <463.6 (Fig. 1b). This suggests that seasonal fluctuations in precipitation and temperature have significant control over the plant richness of the Eastern Himalayas.

The Western Himalayan Example

A decision tree analysis in the Western Himalayas revealed that precipitation of the driest quarter (PDR) < 80 mm has great significance for plant richness, which could minimize its impact with mean annual precipitation >352 mm. This indicates that the plant richness in the Western Himalayas is dependent on water availability, where greater precipitation in the driest quarter is a limiting factor (Panda 2018). However, the plant's survival continues even at mean annual precipitation <352 mm and PDR ≤ 46 mm. The temperature seasonality (TS) is a crucial factor, and >659 would create thermal stress on the plant richness. Alternately, a TS value of

≤ 659 could accelerate the plant richness. This suggests that the fluctuations in seasonal temperatures are crucial in determining the plant richness of the region (Fig. 2a).

A similar decision tree analysis in the Western Himalayas indicating the interactions between variables and plant richness showed a significant correlation between precipitation of the driest quarter (PDR) and plant richness. In general, an increase in precipitation during the driest period (>153 mm) accelerated plant richness. A PDR value ranging between 118 mm and 153 mm was predicted as being crucial for determining plant richness. Precipitation of the driest quarter (≤ 118 mm) influenced plant richness more significantly with a reduced rate of temperature seasonality (i.e., $\leq 659\%$). And for obvious reasons, a high-temperature seasonality strongly regulated plant richness at a low level of precipitation in the driest quarter (Fig. 2a).

The precipitation of the driest quarter between 80 and 118 mm could favor the plant richness in the Western Himalayas subject to the mean annual precipitation of ≤ 1232 mm. While greater precipitation in the driest quarter (118–153 mm) was found to have a strong positive effect on plant richness, its value >153 mm was found to be less limiting for plant richness. A moderate PDR and good mean annual precipitation favored plant richness in the Western

Decision Tree, Fig. 2a Interactions between precipitation of driest quarter (PDR) and temperature seasonality (TS) and plant richness; 'n' describes strengths of each node

Decision Tree, Fig. 2b Interactions between precipitation of driest quarter (PDR) and mean annual precipitation (PAN) and plant richness; 'n' describes strengths of each node

Himalayas. This substantiates the limiting role of water availability in plant richness in dry conditions of the Western Himalayas (Fig. 2b).

Conclusions

A decision tree is a tool for decision making and management in many data mining procedures. This is a machine learning

method that involves both regression and classification principles. The decision tree has many advantages over standard regression or classification owing to its ability to use both categorical and numerical variables and its effectiveness in nonlinear modeling setups. The hierarchical tree structure of a decision tree has a root at its top and leaves or decision nodes at its bottom. The deeper the decision tree, the more complex the model. A decision tree can be nonbinary (e.g., ID3, C4.5) or binary (e.g., CART) and depends on different algorithms for splitting or subsampling. ID3 and C4.5 are based on entropy principles and CART on measures of impurity. Of all of them, CART is the simplest and a very popular algorithm, used in decision tree analysis of recent research. Despite many advantages, the decision tree has problems of instabilities, which can be easily handled by bagging and boosting. Independently, bagging and boosting are weak learners, but when combined, both become strong learners. Some of the good examples of decision tree algorithms involving principles of bagging and boosting for bias-free predictions are random forest, gradient boosting model, and support vector machines, widely implemented in ecological, engineering, scientific, and socioeconomic decision making and planning.

Deep CNN-Based AI for Geosciences

Mehala Balamurali

Australian Centre for Field Robotics, University of Sydney, Sydney, NSW, Australia

Definition

In deep learning, a convolutional neural network (CNN, or ConvNet) is a subset of artificial neural network that is specially used for processing data that has grid-like topology. As the inclusion of “convolutional” in name, these neural networks apply convolution in lieu of standard matrix multiplication in at least one of their layers (Ian Goodfellow 2016).

Introduction

Deep learning along with machine learning are subsets of artificial intelligence. Deep learning algorithms are more state-of-art and unsupervised comparing to machine learning approaches. A deep neural network (DNN) is an artificial neural network (ANN) with multiple layers between the input and output layers (Alzubaidi et al. 2021). Deep learning taught the machine with inputs, and target should be detected and classified after several hidden layer in the output layer (Fig. 1). The deep neural network imitates the neurons, and their connections in our brain on how the information is being received and processed.

There are many deep neural network (DNN) algorithms. Among them **deep convolutional neural networks** are widely used in identifying patterns in images and videos. The gaining popularity in computer vision with deep Learning has been raised and improved with time, mainly the implementation of the convolutional neural network.

CNN can effectively capture the spatial and temporal dependencies of data that has grid-like topology using multiple filters. Unlike other methods where features are hand engineered, in CNN, the features are learned with adequate training.

In recent years, application of convolutional neural networks (CNN) is gaining popularity in the field of Geosciences. CNN would map the input data and make prediction after processing in the layers between. The common

Deep CNN-Based AI for Geosciences, Fig. 1 A deep learning architecture with multiple hidden layers. (Source: Wikimedia c CC)

Deep CNN-Based AI for Geosciences, Fig. 2 A classic CNN structure. (Source: <https://goo.gl/zondfq>)

types of layers can be seen in a classic CNN structure are convolutional layer, pooling layer, and fully connected layer (Fig. 2).

Convolutional Layer

As name suggested, the convolutional layer (Fig. 3) is an important part of the structure of CNN. The process of convolution in this layer extracts the features from the input data. In the image data, the filters known as kernels convolute the weights and heights from the input pixel values and returns the important features in a similar dimension of image or in different dimension.

When the input is RGB images, they are read as pixels as a height x width x depth ($M \times N \times 3$) matrix. The dot product of the corresponding image matrix and a small dimension of

filter matrix with similar depth will return the feature map. The process of sliding filters through the width and the height of the image along the operation of dot multiplication is known as convolution. Different filters retrieve different features, and the outputs are passed to the next layer. With deeper layers, more sophisticated details can be identified.

The parameters of convolution operations are filter size, padding, stride, dilation, and activation function. The left image in the top row of Fig. 3 shows a 3 by 3 filter used with a 5 by 5 image with padding of one that results 5 by 5 image. Padding is used to maintain both output and input image sizes same by padding zeros onto input image in each dimension before the convolution operation. Stride determines how many pixels the filter moves by, in right or down direction. The activation functions used in the hidden layers

Deep CNN-Based AI for Geosciences, Fig. 3 Convolutional layer and kernel movement example [<https://theano-pymc.readthedocs.io>] at row 1 and Examples of activation functions [Shruti Jadon on [Medium.com](https://medium.com)] at row 2

control the learnability of the model from the training data. Hence the selection of activation functions state model prediction. The bottom row of Fig. 3 shows some example of activation functions that are commonly used in computer vision: sigmoid, hyperbolic tangent, rectified linear unit (ReLU), leaky ReLU, Maxout, and exponential linear units (ELU).

Pooling Layer

The pooling layer performs the down sampling using different type of pooling layers and thus combination of convolutional and pooling layers reduce the number of parameters while maintains the feature information. As seen in Fig. 4, max pooling finds the largest value within the selected matrix, the average pooling calculates the average

Deep CNN-Based AI for Geosciences, Fig. 4 Maximum, average, and sum pooling layers

of the values in the selected region, and the sum pooling layer returns the sum of the values within the selected region.

Fully Connected Layers

In CNN architecture, fully connected layers construct the last few layers where all neurons from previous layer are associated to each activation unit of the next layer. Hence these layers are the next time-consuming layers after convolution layers. The output from the last pooling layer or convolution layer is input into the fully connected layer in the flatten format.

Training a Deep CNN Model

CNN models commonly use backpropagation algorithm where the operation finds the kernels in convolution layers and weights of fully connected layers that minimize the difference between the output prediction and given ground truth labels on a training dataset. The learnable parameters are calculated using loss functions and updated using optimization algorithm. The given data with ground truth labels are split into three sets: training data, validation data, and test data. While the model is trained using training data, validation data is used to observe the model performance during training and fine tune the hyper parameters. Test data are further used to evaluate the model performance on unseen data after the model is trained and finetuned.

Transfer Learning

Training a deep learning model needs enormous, labelled data, but those are rarely available in some domains. Transfer learning is one of the alternative approaches that adopts a CNN model which is previously trained on an abundance of natural labelled images. This method has been gaining popularity in many research fields including geosciences, and the exchange of knowledge transfer between natural images and images from geosciences has been continuously studied.

Transfer learning can be established in two different ways. As in Fig. 5b, a pretrained model can be used as a feature extractor by replacing the fully connected layer by any classifiers such as SVM and random forests. On the other hand, as in Fig. 5c, the pre-trained model can be fine-tuned with

labelled data from geosciences by replacing not only the fully connected layer also with some part of the convolutional layers.

Some Commonly Used CNN Architecture

Some of the commonly used deep convolutional neural network architectures in computer vision tasks (Alzubaidi et al. 2021) are below.

AlexNet (Year)

AlexNet consists of eight layers including five convolutional and three fully connected layers. ReLU nonlinearity is implemented after all the layers and followed by overlapping pooling and then local normalization process. An overfitting problem may be occurred by the large number of parameters because AlexNet has 60 million parameters. In order to reduce this problem, data augmentation, principal component analysis (PCA), and dropout methods are implemented.

VGGNet

As the winner of the 2013 ILSVRC competition, VGGNet consisted of 16 to 19 layers, which is significantly deeper compared with the architecture of AlexNet for instance. Small three by three filters are implemented in VGGNet, which sets a trend of network with small filter size to aim to increase depth.

Inception Net/GoogLeNet

From the winning of ILSVRC price in 2014, Inception Net has been developed and has up to version 4 now. Inception v1 (GoogLeNet), which was developed by a team in Google, introduces high-accuracy inception blocks with low complexity. Inception blocks implement different size filters in the same convolutional block to capture various spatial features in different operations. This is a classic feature that continues to the following versions of Inception Net. Inception v2 (BN-Inception) is version 1 with addition batch normalization which copes with internal covariant shift situation. Inception v3 is updated with factorization. Finally, Inception v4 is a pure inception version with no residual connections that could be trained with memory optimization and no need for partitioning.

Deep CNN-Based AI for Geosciences, Fig. 5 (a)

Pretrained model is used as feature extractor (b) or (c) fine-tuning technique

ResNet (2015)

ResNet is considered to implement residual learning to avoid the decrease of performance due to the increasing number of stacking layers. In ResNet, skip connections were implemented between shallow and deep layers to prevent the gradient vanishing and degradation of the model. Additionally, skip connections could skip the redundant layers and maintain the ability of computer vision while ensuring the performance and non-degradation of the model after saturation.

Inception ResNet

Combined with Inception Net and ResNet explained above, the first version, Inception-Resnet-v1 was implemented which is faster but lower accuracy than Inception v3. Adding ReLU as pre-activation unit will make the model go deeper. However, an exceeded number of filters might raise model instability and network death. In the following version, Inception ResNetv2 has much faster training speed and accuracy and similar computational cost as Inception v4.

MobileNet

MobileNet is normally used in mobile vision applications on image classification when the environment has limited resources. MobileNet implemented a small number of parameters with high efficiency. MobileNet is also a good option for portable devices as the size of the model is shrunk.

Applications in Geosciences

In recent years deep CNN models have provided more accurate results and are getting popularity in the field of geosciences. Unlike traditional machine learning approaches that are based on a structured data with carefully selected

attributes, deep CNN can process raw unstructured data themselves within layers of the network. However, deep CNN models rely on large, labeled data. Hence, the first step in the model approach, domain experts' knowledge is needed to robustly train these models with accurate ground truth data.

Classification

Deep CNN applications in geosciences have already been seen in many applications in earth and planetary sciences. Among them, deep CNN models have been used as image classification tools for rock images classification and reservoir classification (Evgeny et al. 2020) and interpreting lithology and subsurface from drill cores (De Lima et al. 2019). As the seismic data is usually logged in the time-space domain, transforming this data into gray scale images let the researchers to utilize the advantage of CNN models to studying stratigraphic natures.

Segmentation

Singh et al. (2020) used state of the art deep CNN models (DeepLab, UNet, DenseNet and SegNet) to segment river surface into water and two types of ice with limited labeled and noisy data. Some other studies used classic image segmentation CNN models to segment faults (Yu and Ma 2021).

Detection

In earth and planetary sciences, geologists found detecting and counting craters are key feature to determine the evolution of planets (DeLatte et al. 2019). Scratch CNN models were used to extract the features from image data and then used them to train the classifiers. On the other hand, models such as GoogLeNet, VGGNet, and ResNet that were pre trained on natural images, have been used to automate the crater detection. Faster R-CNN model was used to localize the craters in the planetary images.

Furthermore, pretrained deep CNN models have been used to perceive the number of mineral grains in sediments or sands using the microscope scans (Julien et al. 2019). Detection of geological features such as faults, layers, dips, boundaries, and cracks have been treated similar to object detection in other computer vision application and were automatically detected using deep CNN models.

Other

Digital elevation maps (DEM) are another vital tool for geologists. Deep CNN models have used to map low- and high-resolution digital elevation map (Jiao et al. 2020). Deep CNN models were used to separate the signals and noise in geophysical data (Zhang et al. 2017). While in many geoscience applications, CNN have used for processing 2D and 3D image data, deep CNN models have been widely adopted by research community to test its capability in interpreting frequency and time domain geophysical data in single dimension (Yu and Ma 2021).

Summary

Deep convolutional neural networks (DCNNs) have accomplished remarkable achievement across diverse domains and have been gaining popularity in geoscience applications. While these models have become leading methods in solving many complex tasks such as image classification and object detection, getting to know the key concepts, advantages, and limitations of these models is crucial, in order to fully utilize them in geoscience research such that the models can provide experts with insights that assist them in decision making.

Definition

Deep learning is a group of machine learning algorithms that has been widely used in geoscience for learning features in high-dimensional data. Selecting a right model and tailoring it to fit for the unique spatial-spectral-temporal nature of the data is key to the successfulness of the application.

Introduction

Deep learning is a group of machine learning algorithms that uses a multilayer neural network architecture to learn a high-dimensional function f from its values at a set of sample

points. By training on a set of sample data X , the goal is to find a sequence of operators $T_1, T_2, \dots, T_h$ such that $T_h \circ T_{h-1} \circ \dots \circ T_1(\tilde{X})$ best approximates $f(\tilde{X})$ for unseen data $\tilde{X}$ sampled from the same distribution as X . The number h is called the depth of the neural network. It is assumed that each operator T_i is of the form

$$X \mapsto (\sigma \circ L_1(X), \sigma \circ L_2(X) \dots, \sigma \circ L_q(X)),$$

where σ is a nonlinear function, and $L_1, L_2, \dots, L_q$ are linear (affine) operators defined as

$$L_i(X) = w_{i1}x_1 + w_{i2}x_2 + \dots + w_{ip}x_p + b_i, \\ X = (x_1, x_2, \dots, x_p).$$

During neural network training, the parameters $w_{i1}, w_{i2}, \dots, w_{ip}$ and b_i are adjusted to minimize the overall approximation error. Approximation theory in mathematics ensures that any high-dimensional continuous function f in a bounded domain can be approximated this way with $h \geq 2$. However, it has been known that in many cases, larger h leads to better performance. When h is large (e.g., $h \geq 7$), the learning algorithm is called deep learning.

Architecture, or more specifically, where each linear operator is defined, determines the performance of a neural network on specific data types. Among the most popular deep learning models are convolutional neural networks, recurrent neural networks, autoencoders, generative adversarial networks, and graph neural networks, each having many successful applications in geoscience.

Convolutional Neural Networks (CNNs)

CNNs are specific kinds of neural networks designed for better capturing spatial dependence among neighboring variables. For digital images, if we use double indices to label the variable (pixel value) at location (i, j) as x_{ij} , then a linear operator in a 2D CNN is defined as $\sum_{(i,j) \in W} c_{ij}x_{ij} + b$, where

W is a $h \times w$ rectangular window centered at (i, j) . Such a linear operator defines a specific mechanism to extract a local feature around (i, j) . CNNs assume such a mechanism is shared by different locations. Thus, each specific local feature only requires $h \times w + 1$ parameters. The small size of $h \times w$ allows a CNN to pack a sequence of such linear operators in one layer. With many layers, a deep CNN can potentially extract many kinds of features in the data, often enabling it to outperform models based on a few hand-crafted features.

The 2D CNNs can be naturally extended to handle multi-dimensional data cubes. For example, hyperspectral imagery (HSI) data are typically presented in 3D cubes, with two spatial dimensions and one spectral dimension of a typical size of over 200. However, the number of variables in a 3D data cube can be typically over a million. Thus, a naïve use of 3D CNNs may face a computational challenge, which is further coupled by the typically smaller number of labeled data points. Below are two representative approaches to use CNNs on HSI.

The first is the multiscale 3D deep CNN model in Qi and Zhang (2020), which leverages two branches of a 3D CNN to extract spatial and spectral features separately. The first branch consists of six 3D convolutional layers interlaced by batch normalizations and ReLu activations, and skip connections between the first, the third, and the fifth layers. It transforms a $9 \times 9 \times 200$ block into 24 spectral features of size $7 \times 7 \times 1$, to be used in the second branch. The second branch crops out two center patches of size $7 \times 7 \times 200$ and $5 \times 5 \times 200$, respectively. The $7 \times 7 \times 200$ patch is transformed by a five-layer 3D CNN with skip connections to 24 features of size $5 \times 5 \times 1$ before being merged with the saved patch of size $5 \times 5 \times 200$ to form 224 features of size $5 \times 5 \times 1$. Additional five convolutional layers with skip layers and fully connected layers are used to finish the classification.

The outstanding performance of the model is derived not only from the task segregation of the two branches, but also from the depth and the skip connections in each branch. Indeed, good performance of CNNs often requires significant depth, which was unfortunately missing in some earlier CNN models for the same HSI data.

A deep CNN requires a powerful GPU and a long time of training. One approach to avoid extensive training is to integrate some existing knowledge into the models. Recent work (He et al. 2019) exemplifies such an approach.

In that article, the authors trained a 2D CNN on hand-crafted feature extractions from the original HSI. The method is as follows: First, apply the maximum noise fraction (MNF) transformation, a transformation that is like principal component analysis (PCA), to reduce the spectral dimension to 20. Next, for each pixel, choose a sequence of M square neighborhoods of varying sizes, centered at the pixel. For a $T \times T$ square neighborhood centered at x_i , find the covariance matrix of the T^2 spectral vectors of dimension L defined by

$$C_{L \times L} = \frac{1}{T^2 - 1} \sum_{j=1}^{T^2} (x_j - \mu)(x_j - \mu)^T$$

where x_j is the spectral vector at pixel x_j in the square neighborhood of x_i , and μ is the mean of the x_j 's. These multiscale covariance maps (MCMs) are of the same shape $T \times T$,

allowing a standard 2D CNN to complete the classification task. The model was reported to have outperformed some other CNN models, as well as some other machine learning models for the same tasks.

While it is worth discussing if the use of these specific MCMs is the best way for capturing spatial-spectral features of HSI, the novelty of this approach is that it introduces a creative way to jointly integrate spatial and spectral information. Note that in this approach, each covariance matrix is the simple average of $g(\mathbf{x}_j - \boldsymbol{\mu})$ over the neighborhood for a specific function g . Thus, the spatial information captured by these features is limited. Nonetheless, this approach opened a door for many meaningful modifications and improvements. For example, one may design different function g or train averaging weights for better integrating spatial information.

Note that the feature maps created in the paper were symmetric matrices. Therefore, half of the information was redundant. Also note the high correlation between neighboring spectral bands is lost in the MNF-transformed spectral vectors. Thus, there seems to be no good reason to use a 2D CNN on these particular features. However, if this approach is applied to spatial-temporal data without a prior nonmonotonic transformation on the temporal axis, CNNs are likely to be beneficial.

Recurrent Neural Networks (RNNs)

In the neural networks we discussed above, the goal was to learn the unknown function f from its behavior at a sequence of data points $X_1, X_2, \dots, X_N$, which were assumed to be independently sampled from the same sample space. In applications, however, we often encounter cases when the sequence of data points $X_1, X_2, \dots, X_N$ are strongly dependent, and more importantly, the function f depends not only on the current data X_N , but also on the previous data $X_1, X_2, \dots, X_{N-1}$. Indeed, this is a typical situation for temporal data, such as daily air pollution, temperature, precipitation, solar radiation, groundwater hydrographs, or co-seismic landslides. Similar dependencies also appear in spatial-spectral data. RNNs are specifically developed to deal with such dependence between sequential data. In a standard neural network, for each input X_N , the neural network uses the operator L to output $\sigma \circ L(X_N)$ without using any information about $\sigma \circ L(X_{N-1})$. In an RNN, the previous output is kept as history h_{N-1} and used together with the current input X_N to produce the new output. Because h_{N-1} was also produced using both X_{N-1} and h_{N-2} , and so on, an RNN has the potential to capture the dependence of the target function on $X_1, X_2, \dots, X_N$.

Careful control of the information flow from history h_{N-1} is of key importance. Without it, an RNN may suffer from the vanishing gradient problem. Long short-term memory

(LSTM) is a specific architecture that facilitates this need. It has a cell unit, an input gate, an output gate, and a forget gate to regulate the information flow. There are many variations of LSTM, such as bidirectional LSTM, convolutional LSTM, graph LSTM, tree-structured LSTM, and gated LSTM. Another very popular RNN is the gated recurrent unit (GRU), which also has a forget gate but not an output gate. GRUs have fewer parameters than LSTMs, making them perform better on smaller datasets, while LSTM may fit large datasets better. However, LSTM may suffer from overfitting. The following two recent articles exemplify the current uses of LSTM and GRU in geoscience research.

In Xiao et al. (2019), the researchers combined adaptive boosting (AdaBoost) ensemble learning with LSTM to overcome the overfitting challenge of LSTM for predicting sea surface temperature using daily satellite time series data at selected sites. Before feeding to the LSTM and AdaBoost, the authors used polynomial fitting to model the seasonal pattern and use it to deseasonalize the raw data. An LSTM is used on the normalized deseasonalized data. Then, adaptive boosting is used on a sequence of weak decision tree regressors produced by a classification and regression tree (CART) to get a new prediction. The two predictions were then averaged to get the final prediction. The combined model significantly outperformed each individual model, as well as other earlier models.

In Hang et al. (2019), the researchers applied RNNs to HSI classification, treating the spectral axis as the time axis. The authors noted that adjacent spectral bands contain a lot of redundant information, while remote spectral bands contain complementary information. Based on this property, the authors built a model with two interconnected GRUs, with the first one removing redundant information within neighboring spectral bands, and the second one learning complementary information from nonadjacent spectral bands. They also used CNN to capture spatial features, as follows. Starting with the HSI data in a 3D cube of size $m \times n \times k$, a small center cube of size $w \times w \times k$ is taken for each pixel and divided into k matrices of size $w \times w$. A 2D CNN is then built to convert each matrix into a d -dimensional feature vector. Then the sequence of k d -dimensional vectors is split into l subsequences $S_1, S_2, \dots, S_l$. Next, each subsequence S_i is fed to the first GRU, outputting an h -dimensional vector F_i^1 . Then, the sequence of l vectors $F_1^1, F_2^1, \dots, F_l^1$ is fed to the second GRU, outputting a vector F^2 . Finally, $F_1^1, F_2^1, \dots, F_l^1$ and F^2 are fed into a final linear layer to generate $l+1$ output vectors with corresponding loss functions $L_1^1, L_2^1, \dots, L_l^1, L^2$. A weighted average of these outputs with weights $w_1^1, w_2^1, \dots, w_l^1, w^2$ is used for final classification, and the same weights are used to define the

loss function
$$L = \frac{1}{l} \sum_{i=1}^l w_i^1 L_i^1 + w^2 L^2$$
 to regulate the

contributions of different outputs. The skip connectivity technique that feeds a copy of the outputs of the first GRU to the last linear layer is a useful technique also used in the 3D CNN introduced earlier. Using weighted loss to softly regulate contributions is also a popular technique.

Autoencoders (AEs)

An autoencoder (AE) is a special kind of neural network in which the output aims to recover the input. If in the middle there is a bottleneck layer with a smaller number of neurons than the input, then the output of this layer can serve a lower dimensional representation of the input data. Thus, AEs usually have a much small bottleneck layer in the middle, and they are often used for dimensionality reduction. If no activation function is used in the network, then such a lower dimensional representation converges to that from PCA. In this sense, AEs have more capacity. Besides generating a lower dimensional representation, a trained AE can also be used for noise reduction and missing value imputation, as the output of an AE preserves essential features of the input. Low-dimensional representations obtained from AEs often outperform those obtained by PCA, as measured by subsequent machine learning algorithms such as clustering. For instance, Mousavi et al. (2019) demonstrated that an unsupervised clustering based on AE can reach the precision of supervised methods on predicting seismic signals without using the labeled data.

Another desired use of AEs is to generate synthetic data by slightly altering the encoded vector in the bottleneck layer. However, a standard AE is not capable of serving that purpose: By randomly altering the encoded vector, the neural network output is often not meaningful. Variational autoencoders (VAEs) have been developed to regulate the distribution of the encoded vectors of meaningful inputs in the latent space. For each input, a VAE produces two vectors μ and σ in the latent space, then randomly selects an independent normal vector (independent among the coordinates) with mean μ and standard deviation σ , and passes them to decoder (the rest part of the neural network). A penalty function is added to encourage all the vectors μ to stay as close to the origin as possible, while keeping the distance between μ_i and μ_j as large as possible for different classes. With this added feature, VAEs can better generate meaningful data like the input, which makes them extremely useful in synthesizing underrepresented data for training machine learning models, as well as in data assimilation (e.g., Canchumuni et al. 2019).

As generative model, VAEs should be compared with generative adversarial networks (GANs), which have also been popularly used in geoscience. For example, GANs have been used to generate synthetic data for 3D seismic facies classification.

Graph Neural Networks (GNNs)

The CNN and RNN models discussed above are very successful in analyzing spatial-spectral-temporal data when there is an underlying Euclidean structure in spatial-spectral-temporal space, meaning that adjacent variables are highly correlated, while remote variables are independent. There are, however, data that are generated from non-Euclidean domains. For example, in the climate data, remote regions may be highly correlated in climate variables such as sea level, temperature, or precipitation. These teleconnections can be represented as a graph with complex adjacency. Indeed, even in Euclidean space, discrete data points may also be expressed using a tree-like structure. GNNs were first studied in late 1990s, and recently they have been actively investigated. In particular, many variants of convolutional graph neural networks (CGNNs), graph variational autoencoders (GAEs), and recurrent graph neural networks (RGNNs) have been developed. In a convolutional layer in GNNs, each node aggregates feature information from its adjacent nodes. After feature aggregation, an activation is applied to the resulting outputs. By stacking multiple layers, each node receives information from all the nodes in the entire graph. To downsize the network, a pooling layer is used to generate a subgraph. At the end of the convolutional layers, a readout layer sums or averages the features in the final subgraph to generate a vector, which is then connected to the fully connected final output layer (Defferrard et al. 2016). GAEs encode a graph and its node information into a vector in latent space and recover the graph data from the encoded vector through reconstructing the graph adjacency matrix (Kipf and Welling 2016). The construction of RGNNs is more involved. For example, because graphs may have different numbers of nodes and different edge connections, to recurrently update the hidden state for each node, a sum operator is needed, and to ensure convergence, certain restrictions must be put on recurrent functions. Detailed descriptions of the construction of RGNN can be found in Scarselli et al. (2009). Because CGNNs, RGNNs, and GAEs are tailored for data in non-Euclidean domains, they are of great potential in geoscience, as exemplified by recent applications (e.g., Khodayar et al. 2020).

Summary

Deep learning models need to be selected based on data. CNNs were designed for better capturing spatial dependence among neighboring variables. RNNs better fit for temporal data in which previous processed data help the current prediction, and they may also be used for spectral data. AEs are often used for dimensionality reduction. VAEs and GANs are extremely useful in synthesizing underrepresented data.

GNNs have great potential in geoscience for studying data in which the relation among the variables has a network structure.

Dendrogram

Rogério G. Negri
São Paulo State University (UNESP), Institute of Science and Technology (ICT), São José dos Campos, São Paulo, Brazil

Definition

A dendrogram is a graph representation able to express a hierarchical structure and the correlation among elements of a dataset.

A dendrogram comprises a tree-based diagram used to depict hierarchical relations between objects. The dissimilarity levels between the objects drive the interpretation of this graph, expressed by the heights of links that generate the clusters.

Figure 1 shows an example of a dendrogram composition regarding the set $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_6\} \subset \mathcal{X}$, whose elements are vectors or tuples defined on a space $\mathcal{X}$. The dissimilarities between the objects are usually computed through a distance measure defined in $\mathcal{X}$ and conveniently chosen according to the application purpose. If $\mathcal{X}$ is a vector space, the Euclidean distance is usually used as the dissimilarity measure. Large values imply larger dissimilarities.

A Clustering Point of View

Naturally, a dendrogram provides an explicit hierarchical clustering configuration in both agglomerative and divisive approaches. Specifically, the agglomerative approach builds the hierarchical structure through consecutive clustering over the dataset until a single cluster is achieved (Fig. 1 – from the smaller to the larger dissimilarity value). In reverse, the divisive approach starts from one single cluster with all elements and then is submitted to successive splits until obtaining clusters composed by a single element (Fig. 1 – from the larger to the smaller dissimilarity value).

Different hierarchical clustering algorithms are found in the literature, for example, the Single Link, Complete Link, Average Link, and Ward's method (Theodoridis and Koutroumbas 2008; Webb and Copsey 2011). Independent of the adopted hierarchical clustering algorithm, the value expressed in a dissimilarity matrix is the basis for the clustering process. Moreover, such matrix is updated, whereas the clusters are merged or split.

In due course, $d(\mathbf{x}_i, \mathbf{x}_k)$ denotes the dissimilarity between the elements $\mathbf{x}_i$ and $\mathbf{x}_k$, where $d: \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}_+$. While $d(\mathbf{x}_i, \mathbf{x}_k) \rightarrow \infty$ represents a large dissimilarity between the compared elements, a larger similarity is observed if $d(\mathbf{x}_i, \mathbf{x}_k) \rightarrow 0$. Furthermore, $d_i(\mathbf{x}_i)$ may be adopted to denote the dissimilarity between the element $\mathbf{x}_i$ to the cluster $\mathcal{G}_j$ as well as $D(\mathcal{G}_j, \mathcal{G}_\ell)$ the dissimilarity between $\mathcal{G}_j$ and $\mathcal{G}_\ell$. Definitions for $d_i(\cdot)$ and $D(\cdot, \cdot)$ are peculiar of each method. The dissimilarity matrix at Table 1 contains the values $d(\cdot, \cdot)$ that gives place to the dendrogram of Fig. 1 using Ward's method.

It is essential to highlight that results from hierarchical clustering do not partition the original dataset into a pre-defined number of subsets but a structure that allows identifying the clusters by choosing a dissimilarity threshold. Figure 2 depicts a reanalysis of the structure at Fig. 1, where thresholds are inserted to define the clusters configuration. Using the τ_1 threshold, two clusters are defined: $\{\mathbf{x}_3, \mathbf{x}_6\}$

Dendrogram, Fig. 1 Example of dendrogram

Dendrogram, Table 1 Example of dissimilarity values between pairs of elements. The lower triangle portion it is omitted since $d(\cdot, \cdot)$ is symmetric

$d(\cdot, \cdot)$	x_1	x_2	x_3	x_4	x_5	x_6
x_1	0	4	13	24	12	8
x_2		0	10	22	11	10
x_3			0	7	3	9
x_4				0	6	18
x_5					0	8.5
x_6						0

Dendrogram, Fig. 2 Examples of thresholds over a dendrogram

and $\{x_1, x_2, x_4, x_5\}$. Regarding τ_4 , five clusters are defined: $\{x_3, x_6\}$, $\{x_1\}$, $\{x_2\}$, $\{x_4\}$ and $\{x_5\}$.

Figure 3a shows a simulated dataset expressed in terms of two components (i.e., a bidimensional vector space). The different colors and shapes denote an expected pertinence regarding four clusters. The Single Link, Complete Link, and Ward's method, using the Euclidean distance as a dissimilarity measure, are applied to cluster the dataset. The results

are presented in the dendrograms of Fig. 3b–d. It is possible to observe that the dissimilarity values are not common among the methods. Moreover, some structures diverge according to the adopted method, as shown by the Complete Link, regarding the dissimilarity structure between the clusters $\{x_3, x_4\}$ and $\{x_2, x_6, x_{10}\}$, when compared to the other methods. The within-clusters dissimilarity proportion also changes, as demonstrated by the height of the links that establishes the clusters

Dendrogram, Fig. 3 An example of dataset and dendrograms from distinct hierarchical clustering methods

$\{x_3, x_4\}$ and $\{x_1, x_2, x_6, x_8, x_{10}\}$ according to the Single Link and Ward's method.

Applications in Geosciences

Recent studies in geosciences have been adopting dendrograms as a support tool for data analysis. Typically, it appears that after the use of hierarchical clustering processes, Bu et al. (2020) perform a study about hydro-chemical groundwater classification. Dendrograms were used to analyze the collected samples, expressed through diverse chemical constituent concentrations, and validate the results through distinct hierarchical clustering methods. Employing registers of resistivity, porosity, spontaneous potential, and gamma-ray profile, Torghabeh et al. (2014) employ dendrograms to understand the hierarchical relation between reservoirs of

gas shale. Based on the geographical distance from the spores' point of origin to a region in Spain, Askew and Wellman (2020) perform an analysis utilizing dendrograms to verify the dispersion of terrestrial plant, zooplankton, and phytoplankton marine communities, which allowed identifying unusual occurrences in distinct places. Garcia et al. (2015) use dendrogram to demonstrate the effectiveness of a clustering method proposed to identify classes in a shallow water environment based on reflectance information measured by remote sensing.

Summary

Dendrograms are useful to represent the relations achieved in a hierarchical clustering process. Such relations are based on dissimilarity values computed over the data clustering

process, represented by the height of the links that draw this graphic representation.

Differential Equations

Sergio Zlotnik and Jaume Soler Villanueva
E.T.S. de Ingeniería de Caminos, Universitat Politècnica de Catalunya, Barcelona, Spain

Definition

The characteristic that makes an equation to be called “differential” is that it describes a relationship between an unknown function and its derivatives. That is, a relationship between a quantity and the variations of the quantity with respect to the independent variables.

Introduction

A large number of natural processes are described by differential equations, and therefore, these equations have been

widely studied in the past and at present. Processes dealing with the conservation of a quantity are governed by a differential equation, making them interesting in countless applications in science and engineering. The movement of hot air generating wind, erosion of the bed of a river, temperature in the Earth’s interior, decay of radioactive elements, deformation of cortical and mantle rocks; all these processes and many others are modeled using differential equations. Continuum mechanics is built upon differential equations, and even discontinuous processes like the generation of fractures or multi-phase flows are usually modeled using differential equations.

Unfortunately, differential equations are very difficult mathematical objects, and we know how to solve just a few of the simplest ones. Although, because of their practical use, many methods have been developed to obtain approximate solutions. An approximate solution is a function that strictly does not fulfill the equations, but it is very close to the actual solution. When the difference between the approximation and exact solution is small and under control, we use the approximation rather than the exact solution for practical scientific and engineering purposes.

The solution of a differential equation is a function. When the equation is used to describe a physical process, the solution is usually a function of space and/or time. For example, let us assume we want to study the decay of a radioactive substance. What we are trying to obtain is how much substance is present at a given moment in time. We want to find a function, $Q(t)$, that describes the amount of radioactive substance at time t . The differential equation that describes (“governs”) the process reads

$$\frac{dQ(t)}{dt} = -k Q(t). \quad (1)$$

This equation provides a relationship between the unknown function, $Q(t)$, and its derivative with respect to time $\frac{dQ(t)}{dt}$ (the rate of change of Q with time). Namely, this equation states that the change of Q in time is proportional to Q with a proportionality constant $-k$.

A second example is the temperature distribution in the Earth’s crust. The temperature $T(x, y, z)$ is a function of the spatial coordinates and, in equilibrium, satisfies

$$-k \left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right) = \rho H, \quad (2)$$

where k is the (constant) thermal conductivity, ρ is the density, and H is a heat source (e.g., the heat generated by the decay of radioactive elements). To simplify the notation, we do not write the dependence on the spatial coordinates of the temperature T in Eq. (2). Both ρ and H can be functions of space,

although Eq. (2) is a simplification of a more general case assuming that k is a scalar and that it does not change in space.

In order to seek the solution of a differential equation, we need to specify the domain in which the equation must be satisfied. That is, the range where the independent variables can move. An example of a domain in Eq. (1) can be any value of t from t_0 to t_{end} . In Eq. (2), the domain is a region in space and is usually denoted by $\Omega \in \mathbb{R}^3$. The spatial domain might take complex shapes, for example, the volume of the crust, from the surface to the Moho, between some latitude and longitude. This volume has a curved surface and might have a very complex base. When the solution depends on both, space and time, then the domain is composed of both the space and time parts.

The solutions of Eqs. (1) and (2) on their corresponding domains are not unique. There is a family of solutions that fulfill each one of the equations. The problem will be mathematically well posed only when the solution is unique. The uniqueness of the solution is obtained when the problem is closed with appropriate boundary conditions. Boundary conditions provide information of the solution at the boundary of the domain, determining which is the actual solution within the family described by the equation. An example of boundary condition for Eq. (1) is $Q(t_0) = 10$, meaning that, at the initial time t_0 the quantity of substance is known and takes the value 10. Boundary conditions for Eq. (2) could be of different kinds, for example, (i) assuming that the temperature at the surface is known and/or (ii) the heat flux at the base of the domain is known. These boundary conditions are reasonable from the physical point of view. Not all the boundary conditions close a problem properly; it is possible that boundary conditions are contradictory or insufficient. Therefore, attention must be paid when specifying them. In practice, when using differential equations to model some physical phenomena, it is usually more challenging to determine the proper boundary conditions, and domain and material properties, than actually solve the equations.

For the complete problem governed by Eq. (1), including the domain and boundary conditions reads, find $Q(t)$ such that

$$\begin{cases} \frac{dQ(t)}{dt} = -k Q(t) & \text{for } t \in [t_0, t_{\text{end}}], \\ Q(t_0) = 10 \end{cases} \quad (3)$$

and similarly, for Eq. (2) the problem reads, find $T(x, y, z)$ such that

$$\begin{cases} -k \left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right) = \rho H & \text{in } \Omega \\ T = T_D & \text{on } \Gamma_D \\ -k \nabla T \cdot \mathbf{n} = f_N & \text{on } \Gamma_N. \end{cases} \quad (4)$$

In Eq. (4), the boundary is denoted by Γ and is partitioned into two nonoverlapping parts: Γ_D and Γ_N . The former is where the solution is known, and the latter is where the heat flow normal to the boundary is known. The vector $\mathbf{n}$ indicates the direction normal to the boundary.

Systems of differential equations, where several of many equations are coupled to each other, are usually found in practice. The book of Zill (2013) provides useful examples, but there is a vast literature available on the topic.

Classification

Differential equations are a large family of equations with different characteristics, and therefore, there are many different ways to classify them. Equation (1) is called an ordinary differential equation (ODE) because all its derivatives are with respect to one variable (in this case, t). When the differential equation has derivatives with respect to several variables, as in Eq. (2), it is called partial differential equation (PDE). This classification is important as the methods used to solve each case are different. Other classifications that are relevant to choosing the solution method follow.

The boundary conditions that close an ODE define two types of problems: in an initial value problem, we start from a known point and seek the solution advancing from that initial point. This is the case of problem (3), and it is the usual case for problems depending on time. Methods to solve initial value problems are called marching methods or time-integration methods. Note that in problem (3) the time domain could be closed (e.g., $t \in [t_0, t_{\text{end}}]$) or could be open (e.g., $t > t_0$). A marching scheme can continue advancing in time while the solution is of interest.

If boundary conditions are specified at different boundary points, e.g., the solution is known at t_0 and t_{end} , then it is called a boundary value problem. The solution in this case describes an equilibrium between the known boundary points, and, in this case, the domain must be closed.

The order of a differential equation is the order of its highest derivative. Equation (1) is order 1, and Eq. (2) is order 2. ODEs of order n can be easily converted in a system of n ODEs of order 1. This is convenient as it is simpler to build methods to solve first-order ordinary equations.

PDEs used in practice to describe natural processes are usually first or second order (fourth-order equations are found in some particular applications but are not as usual).

PDEs of order 2 are classified depending on the kind of physical problem they describe: propagation problems involve space and time domains. Usually, these are initial value problems in time and boundary value problems in

space, and therefore, the complete space solution must be known as initial boundary condition. This particular type of boundary condition is usually called *initial condition*.

Equilibrium problems are steady-state problems (do not involve time) in a closed-space domain. They describe equilibrium solutions. The methods used to solve them are called relaxation methods.

Eigenproblems are special equilibrium problems that depend on space and one parameter. The solution exists only for some special values of that parameter (i.e., eigenvalues). The eigenvalues are not known a priori and must be determined together with the equilibrium configuration of the system.

History

The history of differential equations goes back to the beginning of infinitesimal calculus, when it was realized that most laws of physics actually reduce to differential equations, either ordinary or partial.

In the eighteenth century, differential equations provided an accurate model of the solar system. The Newtonian gravitational interaction between n planets and the sun is a system of $3(n + 1)$ second-order ODEs, equivalent to a system of $6(n + 1)$ first-order equations. Astronomical applications were developed by Euler, Gauss, Lagrange, Laplace, Jacobi, Poincaré, and many others (e.g., see Kline 1990).

PDEs were introduced to model the gravitational Newtonian potential (Laplace equation), motion of fluids, and behavior of elastic bodies. Since the nineteenth century, extraordinary advances have been made in the scientific and technological applications of differential equations. In 1862, James Clerk Maxwell published his electromagnetic field theory based on a set of partial equations, and Einstein's field equations of general relativity are a system of PDE (e.g., see Gray 2021). The solution of very complex ODE and PDE is crucial in modern engineering disciplines such as generation and transmission of electric power, aerodynamics of aircraft, and calculus of structures in civil engineering, just to mention a few.

Solution Methods

Only a few very simple differential equations can be solved by a closed formula involving elementary functions. In this situation, two different routes are possible. First, to somehow simplify the equation and find analytical (i.e., given by mathematical expressions) approximate solutions. This is

the traditional approach taken in astronomy with the theory of small perturbations. Second, to resort to numerical approximations, which give directly the numerical solution but no analytical expression. Numerical methods used just elementary arithmetic operations but had a major difficulty: the number of operations could easily be counted in billions.

A great number of approximate numerical methods have been (and are still being) developed. The name “approximate” must be understood in the sense that the accuracy of the numerical solution can be as high as needed, but the smaller the intended error, the higher the computational effort is. However, the digital computer has made it possible to carry out billions of operations in seconds.

The majority of the methods are based on a “discretization” of the equation, which means approximating the derivatives in the equation by finite quotients of increments. A number of numerical methods for ODEs were developed during the nineteenth century, mostly for astronomical applications. At the end of that century and early twentieth, the Runge–Kutta methods were introduced and are currently the methods of choice except for some very specific problems, for example, computing the orbits of the planets (Sidelmann, 1992). Methods for PDEs have seen a similar evolution, with the only drawback that they usually need a much more extensive computational effort. Around the mid-twentieth century, the finite element methods were introduced (e.g., see Gupta and Meek 1996 for a historical review) and, together with the availability of digital computers, have become the most widely used methods in science and engineering.

There are many introductory and advanced books on numerical methods for differential equations. Some examples worth recommendation are the books of Zienkiewicz et al. (2013) for finite element methods, Hoffman (1992) for finite difference methods, and Leveque (1992) for finite volume methods.

Notation

The notation used to write and explain differential equation is diverse and varies depending on the book, authors, and application field. Each different notation emphasizes a different aspect of the equation or becomes convenient in a specific situation, but all express the same ideas. Here, we present some usual notations to allow the reader to translate them into the form that she/he feels more familiar with.

Scalar numbers are a, b, x, y, i, j (usually i and j are integers and other letters are real valued). Vectorial quantities are denoted as $\mathbf{v}, \bar{\mathbf{v}}$ or in index notation v_i . Tensor

quantities are $\mathbf{K}$, $K_{i,j}$, or $\underline{K}$. Derivatives in ODEs are denoted as $\frac{dQ}{dt}$ and in PDEs as $\frac{\partial u}{\partial x}$ or $\partial_x u$ and, more rarely, (but usual in the context of finite elements) $u_{,x}$. Derivatives with respect to time are usual and have a special (shorter) notation: $\dot{u}$. The most usual operators are gradient and divergence. Gradients are noted as ∇u , $\text{grad } u$, and, using index notation $\frac{\partial u}{\partial x_i}$, $\partial_i u$ or $\partial u_{,i}$, while divergence as $\nabla \cdot \mathbf{u}$, $\text{div } \mathbf{u}$, or in index notation $\partial_i u_i$. One special operator, the Laplacian, is commonly written as $\nabla^2 u$ or Δu .

Conclusion

Differential equations are widely used to model physical phenomena. They describe processes in which the variables are continuous (continuum mechanics is built upon PDEs), but they are sometimes used to model noncontinuous processes (e.g., fractures). Numerical methods are the most common procedure to seek a solution. These numerical solutions are approximate but useful in practice when errors are under control. Caution should be taken in this regard as the decisions taken during the numerical solution procedure might undermine the results and produce inaccurate and non-physical answers.

Digital Elevation Model

Pradeep Srivastava¹ and Sanjay Singh²

¹Earth Sciences, Indian Institute of Technology, Gandhinagar, Gujarat, India

²Signal and Image Processing Group, Space Applications Centre (ISRO), Ahmedabad, GJ, India

Definition and Scope

Digital elevation model (DEM) is a digital, three-dimensional representation of the terrain under consideration. Elevations are defined with respect to a reference surface known as Datum.

Datum is a mathematical representation of the shape and size of the earth. It identifies the origin and orientations of the reference axes for map projection and the reference surface for height measurements. Different datum exists for different regions of the globe, to minimize the error between the geoid (equipotential surface of the earth) and the ellipsoid (mathematical representation for that region). WGS 84 is a universal datum, used as reference ellipsoid by most of the data providers, which is based on Earth Gravitational Model (EGM 2008). The scope of DEM generation in this chapter is to determine elevation above the ellipsoid.

Digital elevation model (DEM) and digital surface model (DSM) are closely related themes used in Earth Sciences to characterize the geometric properties of the Earth's surface. The emphasis in DEM is on determining the elevation of a given point on the Earth's surface above a reference surface (geoid, ellipsoid) and study the behavior of data set of elevation values over a region. In DSM the characteristics of the two (or fractal) dimensional surface of the Earth is studied. In this Encyclopedia we have attempted to treat the two topics as complementary. Accordingly, mathematics of determining the elevation from noncontact (including remotely sensed) observations is given in this chapter on DEM. The mathematics related to characterization of Earth's surface as geometrical or topological artifact is given in the chapter titled digital surface model (DSM).

Introduction

The non contact observations (from satellite, areal, UAV, or terrestrial observations) form the data sets for determining the elevation of the ground point above a given reference surface (Florinsky 2016). The discipline catering to stereo observations and determination of three-dimensional coordinates from these observations is called (Aerial, Satellite, Structure from Motion) Photogrammetry.

Under ideal conditions the elevation h can be computed simply by knowing the stereoscopic parallax as given in Eq. 1.

$$h = H - B * f / p \quad (1)$$

where B is base length, H is height of the platform, f is focal length of the camera and p is the absolute parallax.

The relation of height accuracy versus B/H is given in Eq. 2.

$$\Delta h = \Delta s / \left(\frac{B}{H} \right) \quad (2)$$

Here Δs is the error in identification of pixel and Δh is the error in height.

Extracting Elevation/3D Coordinates from Stereo Imagery: A Generic Photogrammetric Data Adjustment Approach

A photogrammetric approach to determine heights involves (a) determination of position and orientation of the platforms (airborne, satellite, UAV/Drones) followed by (b) computation of heights using the precise knowledge of the orientation. The reconstruction of stereo model depends upon the platform and sensor (frame or line scanner) used to acquire stereo imagery. Bundle adjustment is a technique, which tries to reconstruct the imaging geometry for all bundles of rays emanating from the ground to the sensor at one go. This technique includes modeling of all orientation parameters, viz., orbit, attitude, and camera geometry, and adjusts them simultaneously using precise imaging geometry in the presence of a set of limited GPS observed highly accurate control points and initial knowledge of all parameters, resulting in improvement of interior, exterior orientation parameters, and generating ground coordinates of the conjugate points simultaneously (Gopala Krishna and Lehner 1994; Grodecki et al. 2004; Dave 2013). The possible parameters that can be adjusted during block adjustment are as follows:

Interior orientation parameters

- Focal length f
- Principle point coordinates (x, y)

Exterior orientation parameters

- Orbit parameters (Position (X, Y, Z) , Velocity Vector $(Xdot, Ydot, Zdot)$ as a function of time (for satellite-based platforms).

- Attitude parameters (Roll, Pitch and Yaw). They vary as a function of time for satellite-based platforms.

Ground Coordinates

- Ground coordinates of the conjugate points (X, Y, Z)

The relationship between the ground feature and corresponding point along with acquisition location or perspective center is specified by collinearity equations. The observation equations are derived by linearizing the collinearity condition equations with respect to each of the parameters. Two observation equations are obtained for each ground point in one image.

The combined form of observation equations, treating orientation parameters and ground coordinates as unknown, can be written as Eq. (3).

$$\begin{aligned} & \left(\frac{\partial E1}{\partial \alpha_0} \right)^0 \Delta \alpha_0 + \left(\frac{\partial E1}{\partial \alpha_1} \right)^0 \Delta \alpha_1 + \left(\frac{\partial E1}{\partial \beta_0} \right)^0 \Delta \beta_0 + \left(\frac{\partial E1}{\partial \beta_1} \right)^0 \Delta \beta_1 \\ & + \left(\frac{\partial E1}{\partial \gamma_0} \right)^0 \Delta \gamma_0 + \left(\frac{\partial E1}{\partial \gamma_1} \right)^0 \Delta \gamma_1 + \left(\frac{\partial E1}{\partial X} \right)^0 \Delta X \\ & + \left(\frac{\partial E1}{\partial Y} \right)^0 \Delta Y + \left(\frac{\partial E1}{\partial Z} \right)^0 \Delta Z + V_{L_j} = -E1^0 \\ & \left(\frac{\partial E2}{\partial \alpha_0} \right)^0 \Delta \alpha_0 + \left(\frac{\partial E2}{\partial \alpha_1} \right)^0 \Delta \alpha_1 + \left(\frac{\partial E2}{\partial \beta_0} \right)^0 \Delta \beta_0 \\ & + \left(\frac{\partial E2}{\partial \beta_1} \right)^0 \Delta \beta_1 + \left(\frac{\partial E2}{\partial \gamma_0} \right)^0 \Delta \gamma_0 + \left(\frac{\partial E2}{\partial \gamma_1} \right)^0 \Delta \gamma_1 \\ & + \left(\frac{\partial E2}{\partial X} \right)^0 \Delta X + \left(\frac{\partial E2}{\partial Y} \right)^0 \Delta Y + \left(\frac{\partial E2}{\partial Z} \right)^0 \Delta Z + V_{S_j} = -E2^0 \end{aligned} \quad (3)$$

where V_{L_j} and V_{S_j} are residuals along line and pixel directions to account for random errors, $(\alpha_0, \alpha_1, \dots, \beta_0, \beta_1, \dots, \gamma_0, \gamma_1, \dots)$ are the unknown orientation parameters, (X, Y, Z) are ground coordinates to be determined.

Each point in a given image will give two equations (4).

$$\begin{matrix} V_i & + & B_{I_{ij}} & \Delta I_i & + & B_{O_{ij}} & \Delta O_j & = & \epsilon_{ij} \\ (2,1) & & (2,6) & (6,1) & & (2,3) & (3,1) & & (2,1) \end{matrix} \quad (4)$$

V_i denotes the corrections needed to account for the random error. The subscript I is used to denote corrections to the orientation parameters and subscript O is used to denote corrections to the ground coordinates.

Assuming there are n points which are imaged in m images, the system of equations using Eq. (4) can be written as

$$\begin{aligned}
& \begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ \vdots \\ V_n \end{bmatrix} + \begin{bmatrix} B_{I_1} \\ B_{I_2} \\ B_{I_3} \\ \vdots \\ B_{I_n} \end{bmatrix} \Delta_I \\
& + \begin{bmatrix} B_{O_1} & & & \\ & B_{O_2} & & \\ & & B_{O_3} & \\ & & & \ddots \\ & & & & \ddots \end{bmatrix} \begin{bmatrix} \Delta_{O_1} \\ \Delta_{O_2} \\ \Delta_{O_3} \\ \vdots \\ \Delta_{O_n} \end{bmatrix} \\
& = \begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \epsilon_3 \\ \vdots \\ \epsilon_n \end{bmatrix}
\end{aligned}$$

i.e.,

$$\begin{aligned}
& \begin{matrix} V & B_I & \Delta_I & B_O & \Delta_O \\ (2mn, 1) & (2mn, 6m) & (6m, 1) & (2mn, 3n) & (3n, 1) \end{matrix} \\
& + \\
& \begin{matrix} \epsilon \\ (2mn, 1) \end{matrix}
\end{aligned} \quad (5)$$

Similarly, observation equations for orientation parameters (Eq. (6)) and ground coordinates (Eq. (7)) can be stacked as

$$\begin{matrix} V_I & -\Delta_I & = C_I \\ (6m, 1) & (6m, 1) & (6m, 1) \end{matrix} \quad (6)$$

$$\begin{matrix} V_O & -\Delta_O & = C_O \\ (3n, 1) & (3n, 1) & (3n, 1) \end{matrix} \quad (7)$$

Thus, combining Eqs. (5), (6), and (7) gives a complete mathematical model of the photogrammetric block adjustment problem.

$$V + B_I \Delta_I + B_O \Delta_O = \epsilon$$

$$V_I - \Delta_I = C_I$$

$$V_O - \Delta_O = C_O \quad (8)$$

Expressing this equation as a single matrix equation, we have

$$\begin{aligned}
& \begin{bmatrix} V \\ V_I \\ V_O \end{bmatrix} + \begin{bmatrix} B_I & B_O \\ -1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} \Delta_I \\ \Delta_O \end{bmatrix} = \begin{bmatrix} \epsilon \\ C_I \\ C_O \end{bmatrix} \\
& \bar{V} + \bar{B} \Delta = \bar{C} \quad (9)
\end{aligned}$$

Let $\bar{W}$ be a weight matrix.

$$\bar{W} = \begin{bmatrix} W & & \\ & W_I & \\ & & W_O \end{bmatrix}$$

where W is $(2mn, 2mn)$ matrix for weight of collinearity condition. W_I is $(6m, 6m)$ matrix for weight of orientation parameters and W_O is $(3n, 3n)$ matrix for weight of the object-space coordinates

A least square solution of the model in above equation results in the following normal equation:

$$(\bar{B}^T \bar{W} \bar{B}) \Delta = \bar{B}^T \bar{W} \bar{C} \quad (10)$$

The set of normal equation may be expressed as

$$N \Delta = K \quad (11)$$

The following interesting observations can be made from the Eq. (11) (Slama 1980).

- The N matrix is symmetrical about the principal diagonal.
- The upper left-hand corner of the N matrix consists of (6×6) – submatrices along the principal diagonal. Each matrix is corresponding to one particular image, and all the other elements outside of these submatrices are zero.
- The lower right-hand corner of the N matrix consists of (3×3) – submatrices along the principal diagonal. Each matrix is corresponding to particular point, and all the other elements outside of these submatrices are zero.
- The contribution of each set of the Block Adjustment observation equations can also be identified within the normal equation.

Equation (11) represents normal equation. It contains the set of equations which is represented in the form of matrix as follows:

$$\begin{matrix} N & \Delta & = K \\ (6m + 3n, 6m + 3n) & (6m + 3n, 1) & (6m + 3n, 1) \end{matrix} \quad (12)$$

The **N** matrix is a sparse and is not well conditioned.

These two issues are to be accounted in the implementation for solving normal equations. The direct solution of this set of equations will involve solving $(6m + 3n)$ simultaneous equations. Even for a small block of photographs, the size of the normal equation can become very large making the solution impractical. Instead of solving large matrix in a single shot, the above set of equations are further reduced in smaller sizes and solve by substitution method. The unknowns are obtained or refined iteratively till the convergence is achieved.

Satellite Photogrammetry for Line-scanner Imagery

This section deals with DEM generation using stereo images acquired by optical linear array sensors on-board satellite platforms like SPOT-5, Cartosat-1 which are dedicated satellites acquiring stereo imagery (Srivastava et al. 2007). The photogrammetric models are used to mathematically describe the relationship between ground coordinates and image coordinates (Srivastava et al. 2020; Srinivasan et al. 2013; Dave 2013). The two popular modeling approaches are: (i) Rigorous Sensor Model (physical model called RSM) and (ii) Rational Polynomial Model (RPM). Either of the models is used to reconstruct a precise relationship between 2D images to 3D ground coordinates using orbit and attitude data, available as part of ancillary data. The core of the modeling is the establishment of the precise viewing direction or look vector in the presence of distortions arising from camera tilt, spacecraft motion and orientation, earth rotation and curvature in addition to surface relief through series of coordinate transformations specially chosen for each mission with proper definition and conventions.

Important points to be considered in line scan imagery obtained from satellite borne optical sensors (Srivastava and Gopala Krishna 2020):

- **Orbital Constraints:** The position of the imaging camera mounted on a satellite follows its orbit so that the camera positions corresponding to imaged lines are related by an orbital constraint. As is well known from orbital mechanics, the orbital path of a free flying satellite around the Earth is an ellipse in an inertial coordinate system. In an Earth-centered Earth-fixed coordinate system

(a coordinate system used for providing ground position), it is a complex curve in space.

- **Attitude behavior within a scene:** Attitude is the orientation of the imaging camera with respect to the ground coordinate system. This is a straightforward concept when working with aerial frame photographs. There is only one set of angles (roll, pitch, yaw, or quaternions) which represent the attitude of imaging geometry. Usually the value is initiated to zeros and determined as part of photogrammetric adjustment. In this case, the value is changing with every imaging line, and the relation between body coordinate system and the ECEF ground coordinate system is complex, even some transformations are not orthogonal. The attitude, as understood by and as measured by the onboard Attitude Orbit Control System (AOCS), is the orientation of the body coordinate system with respect to the orbital coordinate system and not with respect to the ground coordinate system as understood in photogrammetry. The remaining relation needs to be worked out from the data on orbital position of the satellite at the time.

This section deals with the photogrammetric models and their applications in deriving orientation parameters and Digital Elevation Models.

Rigorous Sensor Model (RSM)

The RSM is the physical model which is based on the collinearity condition which states that the perspective center, image point and the corresponding object space point all lie in same line (Fig. 1).

Mathematically it can be stated as

$$\begin{bmatrix} f \\ -x \\ -y \end{bmatrix} = KM \begin{bmatrix} X_A - X_S \\ Y_A - Y_S \\ Z_A - Z_S \end{bmatrix} \quad (13)$$

Digital Elevation Model, Fig. 1 Imaging sensor geometry

where $\begin{bmatrix} f \\ -x \\ -y \end{bmatrix}$ is the focal plane coordinates, $\begin{bmatrix} X_A \\ Y_A \\ Z_A \end{bmatrix}$ are the ground coordinates and $\begin{bmatrix} X_S \\ Y_S \\ Z_S \end{bmatrix}$ are the coordinates of the perspective centre. M1, M2, and M3 are the first, second, and third rows of the rotation matrix M.

Coordinate Systems

This section discusses the various coordinate systems required to establish the transformations. The following coordinate systems are used to carry out the required transformation in the imaging sensor model (Gopala et al. 2010; Srinivasan et al. 2013):

- (i) Earth-centered Inertial coordinate system (ECI)
- (ii) Earth-centered Earth Fixed system (ECEF)
- (iii) Local orbital coordinate system
- (iv) Spacecraft body coordinate system
- (v) Image or Focal Plane coordinate system (image space).

Usually both mappings, that is, relating image to ground coordinates and vice versa, are required for data processing towards DEM generation. Details on how the above systems are related to one another are discussed in the following sections.

Estimation of Image Coordinates from Ground Coordinates

The sequence of transformations for computing the image coordinates using ground coordinates as inputs is as follows:

- Latitude, Longitude, and Height (ϕ, λ, h) of a ground point is converted to the Cartesian ECEF coordinate system.
- Transformation from ECEF to ECI coordinates uses sideral angles.
- ECI coordinates are transformed to orbital frame of reference using state vectors (X, Y, Z – position and $\dot{X}, \dot{Y}, \dot{Z}$ – velocity).
- Orbital system coordinates to body frame coordinate system using the attitude.
- The body frame coordinate system to Sensor (imaging payload or camera) is carried out using the spacecraft mounting angles and alignment angles.
- Sensor frame to image plane or Focal plane coordinate system is performed using the payload geometry of the sensor under consideration and then is converted to image coordinate system (time or scanline, pixel).

Since the ‘time’ is the unknown parameter in estimation of image coordinates, direct solution is not possible but estimated iteratively using collinearity condition between two known times.

Transformation matrix **M** is a product of three rotation matrices:

M = **RL** * **RA** * **RO**, where

RL is look angle rotation matrix transformation from spacecraft body coordinate system to sensor image coordinate system.

RA is attitude rotation matrix transformation from orbital coordinate system to spacecraft body coordinate system and it is given as a product of three rotations Rpitch, Rroll, and Ryaw.

RA = Ryaw * Rroll * Rpitch

RA matrix is filled by using orbit to body attitude in True of Date (TOD) reference system, and **RO** is orbit rotation matrix transformation from ECI coordinate system to orbital coordinate system.

Estimation of Ground Coordinates from Image Coordinates

This process is the reverse of the ground to image computation process mentioned in the above section. This is directly using the collinearity equations. As such, this is the solution of the look vector intersecting the earth surface (ellipsoid) using the above sequence of transformation from sensor frame to geocentric and then computing the ground latitude, longitude. Precise height of the object is found out using stereo imaging geometry. The above image to ground relation is considered as “Rigorous Sensor Model” of an image and is used for transformation between 2D image space and the 3D object space. It includes the physical parameters about the camera, such as focal length, principal point location, pixel size, lens distortions, and orientation parameters of the image such as position and attitude.

Rational Polynomial Model (RPM) (Grodecki 2001; Tao and Ha 2001; Sanjay et al. 2008)

In this approach, the complex imaging geometry involving orbit, attitude, camera geometry, etc. is modeled through Rational Polynomial Coefficient (RPC). Each scanline number can be expressed as a function of ground coordinates in terms of ratio of cubic polynomials. The constant term in the denominator is taken as 1. So for a given scanline number, we have

$$scan = \frac{P_1(X, Y, Z)}{P_2(X, Y, Z)} \quad (14)$$

Where,

$$\begin{aligned} P_1(X, Y, Z) &= \sum_{i,j,k=0}^{i+j+k \leq 3} a_{ijk} X^i Y^j Z^k, \quad P_2(X, Y, Z) \\ &= \sum_{i,j,k=0}^{i+j+k \leq 3} b_{ijk} X^i Y^j Z^k, \quad b_{000} = 1 \end{aligned}$$

Similarly each pixel number can also be expressed as a function of ground coordinates as ratio of cubic polynomials, that is,

$$pixel = \frac{P_3(X, Y, Z)}{P_4(X, Y, Z)} \quad (15)$$

Where,

$$\begin{aligned} P_3(X, Y, Z) &= \sum_{i,j,k=0}^{i+j+k \leq 3} c_{ijk} X^i Y^j Z^k, \quad P_4(X, Y, Z) \\ &= \sum_{i,j,k=0}^{i+j+k \leq 3} d_{ijk} X^i Y^j Z^k, \quad d_{000} = 1 \end{aligned}$$

Here (X, Y, Z) are the normalized object space coordinates, that is, normalized latitude, longitude, and height, respectively. *scan* and *pixel* are the normalized scanline number and pixel number between $(-1, +1)$.

Some Applications of Photogrammetric Adjustment Are:

Reconstruction of Attitude Behavior

Derived collinearity equations from Eq. (13) can be expressed as

$$E1 = (xM1 + fM2) [\overline{XA} - \overline{XS}] \quad (16)$$

$$E2 = (yM1 + fM3) [\overline{XA} - \overline{XS}] \quad (17)$$

where $\overline{XA} = \begin{bmatrix} X_A \\ Y_A \\ Z_A \end{bmatrix}$, $\overline{XS} = \begin{bmatrix} X_S \\ Y_S \\ Z_S \end{bmatrix}$ and $M1, M2$, and $M3$ are the first, second and third rows of the rotation matrix M .

Rotation matrix M is the function of orbit as well as attitude, as explained in the previous section. The attitude refinement model is normally assumed to be

$$roll = originalroll + \alpha_0 + \alpha_1 * time + \alpha_2 * time^2 + \dots$$

$$pitch = originalpitch + \beta_0 + \beta_1 * time + \beta_2 * time^2 + \dots$$

$$yaw = originalyaw + \gamma_0 + \gamma_1 * time + \gamma_2 * time^2 + \dots$$

where, $(\alpha_0, \alpha_1, \dots, \beta_0, \beta_1, \dots, \gamma_0, \gamma_1, \dots)$ are the time varying error model coefficients for roll, pitch, and yaw, respectively. First the Eqs. (16) and (17) are linearized by Taylor's series expansion (Eqs (18) and (19)) which will contain differentials of refinement parameters chosen for modelling.

$$\begin{aligned} &\left(\frac{\partial E1}{\partial \alpha_0}\right)^0 \Delta \alpha_0 + \left(\frac{\partial E1}{\partial \alpha_1}\right)^0 \Delta \alpha_1 + \left(\frac{\partial E1}{\partial \beta_0}\right)^0 \Delta \beta_0 \\ &+ \left(\frac{\partial E1}{\partial \beta_1}\right)^0 \Delta \beta_1 + \left(\frac{\partial E1}{\partial \gamma_0}\right)^0 \Delta \gamma_0 + \left(\frac{\partial E1}{\partial \gamma_1}\right)^0 \Delta \gamma_1 = -E1^0 \end{aligned} \quad (18)$$

$$\begin{aligned} &\left(\frac{\partial E2}{\partial \alpha_0}\right)^0 \Delta \alpha_0 + \left(\frac{\partial E2}{\partial \alpha_1}\right)^0 \Delta \alpha_1 + \left(\frac{\partial E2}{\partial \beta_0}\right)^0 \Delta \beta_0 \\ &+ \left(\frac{\partial E2}{\partial \beta_1}\right)^0 \Delta \beta_1 + \left(\frac{\partial E2}{\partial \gamma_0}\right)^0 \Delta \gamma_0 + \left(\frac{\partial E2}{\partial \gamma_1}\right)^0 \Delta \gamma_1 = -E2^0 \end{aligned} \quad (19)$$

The equation (9) which describes the general formulation of block adjustment can be reduced to include only the refinement parameters for attitude, resulting in small set of equations for a single image.

$$[V] + [B_I][\Delta_I] = [e] \quad (20)$$

Using the above equation, the refinement parameters for attitude are computed as least squares solution. The parameters are computed iteratively and hence the corrections to the initial approximate values are updated at each iteration.

Reconstruction of Orbital Parameters

In orbit-based space resection, the orbital parameters inclination, longitude of ascending node, and true anomaly are chosen for modeling. The collinearity equations (16) and (17) are linearized by Taylor series expansion with respect to orbital elements. The orbit model is chosen as

$$\begin{aligned} \text{inclination} &= \text{originalinclination} + i_0 + i_1 * \text{time} \\ &+ i_2 * \text{time}^2 + \dots \end{aligned}$$

$$\begin{aligned} \text{longitudeofascendingnode} &= \text{originallongitudeofascendingnode} \\ &+ \Omega_0 + \Omega_1 * \text{time} + \Omega_2 * \text{time}^2 \\ &+ \dots \end{aligned}$$

$$\begin{aligned} \text{trueanomaly} &= \text{originaltrueanomaly} + F_0 + F_1 * \text{time} + F_2 \\ &* \text{time}^2 + \dots \end{aligned}$$

where, $(i_0, i_1, \dots, \Omega_0, \Omega_1, \dots, F_0, F_1, \dots)$ are the time varying error model coefficients for inclination, longitude of ascending node, and true anomaly, respectively.

The error model for orbit is assumed as a time varying components. The parameters (deltas) are computed by least square method from the following equations:

$$\begin{aligned} & \left(\frac{\partial E1}{\partial i_0} \right)^0 \Delta i_0 + \left(\frac{\partial E1}{\partial i_1} \right)^0 \Delta i_1 + \left(\frac{\partial E1}{\partial \Omega_0} \right)^0 \Delta \Omega_0 \\ & + \left(\frac{\partial E1}{\partial \Omega_1} \right)^0 \Delta \Omega_1 + \left(\frac{\partial E1}{\partial F_0} \right)^0 \Delta F_0 + \left(\frac{\partial E1}{\partial F_1} \right)^0 \Delta F_1 = -E1^0 \end{aligned} \quad (21)$$

$$\begin{aligned} & \left(\frac{\partial E2}{\partial i_0} \right)^0 \Delta i_0 + \left(\frac{\partial E2}{\partial i_1} \right)^0 \Delta i_1 + \left(\frac{\partial E2}{\partial \Omega_0} \right)^0 \Delta \Omega_0 \\ & + \left(\frac{\partial E2}{\partial \Omega_1} \right)^0 \Delta \Omega_1 + \left(\frac{\partial E2}{\partial F_0} \right)^0 \Delta F_0 + \left(\frac{\partial E2}{\partial F_1} \right)^0 \Delta F_1 = -E2^0 \end{aligned} \quad (22)$$

The equation (9) can be reduced to include only the refinement parameters for orbit, resulting in

$$[V] + [B_I][\Delta_I] = [\epsilon] \quad (23)$$

Using the above system of equation, the refinement parameters for orbit can then be computed by using least squares. The parameters are computed iteratively and hence the corrections to the initial approximate values are updated at each iteration.

Corrections to Viewing Geometry with RPCs

Correction parameters to scan and pixel directions are determined from ground control (Groddecki and Dial 2003) to express the object space to image space relationship.

The RPC-based space resection model equation for each GCP can be written as follows:

$$\text{Scan} = \Delta g + g(\phi, \lambda, h) \text{Pixel} = \Delta h + h(\phi, \lambda, h) \quad (24)$$

where,

Scan and Pixel are measured line and sample coordinates of the GCP with object space coordinates (ϕ, λ, h) , and Δg and Δh are the adjustable functions which model the difference between the measured and the nominal line and sample coordinates of GCP.

g and h are the denormalized RPC models for image i for given line and sample,

$$\begin{aligned} g(\phi, \lambda, h) &= L(\phi, \lambda, h) \cdot \text{SCAN_SCALE} \\ &+ \text{SCAN_OFF}h(\phi, \lambda, h) \\ &= S(\phi, \lambda, h) \cdot \text{PIXEL_SCALE} + \text{PIXEL_OFF} \end{aligned} \quad (25)$$

Δg and Δh are the adjustable functions

$$\Delta g = a_0 + a_S \cdot \text{Pixel} + a_L \cdot \text{Scan} + a_{SL} \cdot \text{Pixel} \cdot \text{Scan} + \dots$$

$$\Delta h = b_0 + b_S \cdot \text{Pixel} + b_L \cdot \text{Scan} + a_{SL} \cdot \text{Pixel} \cdot \text{Scan} + \dots$$

where, $a_0, a_S, a_L, \dots$ and $b_0, b_S, b_L, \dots$ are the image adjustment parameters for scan and pixel direction, respectively. Truncated polynomial model to linear model is as shown below

$$\Delta g = a_0 + a_S \cdot \text{Pixel} + a_L \cdot \text{Scan}$$

$$\Delta h = b_0 + b_S \cdot \text{Pixel} + b_L \cdot \text{Scan} \quad (26)$$

The adjustment parameters a_0, a_S, a_L and b_0, b_S, b_L are determined during the RPC-based space resection process.

3D Point Coordinates Computation

DEM with RSM The conjugate points (image point pair) are used in this process to generate 3D coordinates. The line connecting the perspective centers, object point, and corresponding image point from individual cameras are made to intersect in this process by space intersection models to derive the 3D ground coordinates.

Initial ground coordinates are computed by the intersection of rays from two cameras. The initial ground coordinates are iteratively refined by least squares method. For one conjugate point out of doublet or triplet of overlapping images, the system of equation would be

$$\begin{aligned} & \left(\frac{\partial E1}{\partial X} \right)^0 \Delta X + \left(\frac{\partial E1}{\partial Y} \right)^0 \Delta Y + \left(\frac{\partial E1}{\partial Z} \right)^0 \Delta Z \\ & = -E1^0 \quad \left(\frac{\partial E2}{\partial X} \right)^0 \Delta X + \left(\frac{\partial E2}{\partial Y} \right)^0 \Delta Y \\ & \quad + \left(\frac{\partial E2}{\partial Z} \right)^0 \Delta Z \\ & = -E2^0 \end{aligned} \quad (27)$$

where (X, Y, Z) are the ground coordinates of the conjugate point.

One ground point corresponding to the same feature in two overlapping images will give four equations which will be solved iteratively to obtain the final ground coordinates.

Equation (9) can be reduced to include only the refinement parameters for ground coordinates, resulting in

$$[V] + [B_O][\Delta_O] = [\epsilon] \quad (28)$$

DEM with RPM Separate sets of RPCs, corresponding to separate images, model the mappings between the ground coordinates and the image coordinates. The rational functions w.r.t scan and pixel direction can be given as

$$\begin{aligned}\text{Scan} &= p(\emptyset, \lambda, h) \\ \text{Pixel} &= r(\emptyset, \lambda, h)\end{aligned}\quad (29)$$

Where,

$$\begin{aligned}p(\emptyset, \lambda, h) &= \frac{N_{\text{scan}}(X, Y, Z)}{D_{\text{scan}}(X, Y, Z)} * \text{scan_scale} \\ &\quad + \text{scan_offset } r(\emptyset, \lambda, h) \\ &= \frac{N_{\text{pixel}}(X, Y, Z)}{D_{\text{pixel}}(X, Y, Z)} * \text{pixel_scale} + \text{pixel_offset}\end{aligned}\quad (30)$$

Here $(\emptyset, \lambda, h)$ are object-space coordinates of a point under consideration and (X, Y, Z) are the normalized ground coordinates of the same point which can be obtained from $(\emptyset, \lambda, h)$

$N_{\text{scan}}(X, Y, Z)$, $D_{\text{scan}}(X, Y, Z)$ are the numerator and denominator of the rational polynomial in scan direction, respectively

$N_{\text{pixel}}(X, Y, Z)$, $D_{\text{pixel}}(X, Y, Z)$ are the numerator and denominator of the rational polynomial in pixel direction, respectively

Corresponding linearized equations can be written as

$$\begin{aligned}\text{scan} &= p(\emptyset_0, \lambda_0, h_0) + \left[\frac{\partial p}{\partial z^T} \right]_{z=z_0} dz \\ \text{pixel} &= r(\emptyset_0, \lambda_0, h_0) + \left[\frac{\partial r}{\partial z^T} \right]_{z=z_0} dz\end{aligned}\quad (31)$$

Where,

$$z = [\emptyset \quad \lambda \quad h]^T$$

z_0 is the value of z at initial values of $(\emptyset, \lambda, h)$

In the case of two overlapping images, Eq. (31) can be written as

$$\begin{aligned}\text{Scan}_1 &= p_1(\emptyset, \lambda, h) \\ \text{Pixel}_1 &= r_1(\emptyset, \lambda, h) \\ \text{Scan}_2 &= p_2(\emptyset, \lambda, h) \\ \text{Pixel}_2 &= r_2(\emptyset, \lambda, h)\end{aligned}\quad (32)$$

Hence,

$$Adz = B\quad (33)$$

where,

$$A = \begin{bmatrix} \frac{\partial p_1}{\partial z^T} & \frac{\partial r_1}{\partial z^T} & \frac{\partial p_2}{\partial z^T} & \frac{\partial r_2}{\partial z^T} \end{bmatrix}_{z=z_0}^T$$

$$dz = [d\emptyset \quad d\lambda \quad dh]^T \text{ and}$$

$$B = \begin{bmatrix} \text{Scan}_1 \\ \text{Pixel}_1 \\ \text{Scan}_2 \\ \text{Pixel}_2 \end{bmatrix} - \begin{bmatrix} p_1(\emptyset_0, \lambda_0, h_0) \\ r_1(\emptyset_0, \lambda_0, h_0) \\ p_2(\emptyset_0, \lambda_0, h_0) \\ r_2(\emptyset_0, \lambda_0, h_0) \end{bmatrix}$$

Equation (33) is solved by least squares. It is solved iteratively by adding delta values to the initial values of the ground coordinates.

Photogrammetric Adjustment of Aerial Stereo Photo Blocks

The images acquired with the aerial platforms are captured by frame cameras (analog or digital) and have large overlaps (of the order of 60%). Aerial campaigns are planned in such a way that sequential frame images have large overlaps as well as sidelaps (of the order of 40%). Each frame can be expressed as a bundle in the collinearity model. The independent models are adjusted using the block adjustment technique as described earlier in section “[Extracting Elevation/3D Coordinates from Stereo Imagery: A Generic Photogrammetric Data Adjustment Approach](#).” Control points/Tie points in the overlap and sidelap regions ensure the consistency between the adjacent images. Many other parameters can be included during the formulation of the original problem. Convergence criterion for each of the parameters is adjusted while forming the weight based on the need for its refinement. DEM is obtained as a product of photogrammetric adjustment of the blocks of images.

DEMs from Unmanned Aerial Vehicles (UAV) Using Structure from Motion (SfM) Approach

SfM is a photogrammetric technique where a set of two-dimensional images sequences are used to create three-dimensional structures (Iglhaut et al. 2019; Westoby et al. 2012). These images are typically acquired by the digital frame cameras on-board UAVs and are acquired as the platform moves with large overlaps between the images. The main advantage of this technique is that it can work with both calibrated and uncalibrated cameras. Both pose/orientation and 3D coordinates can be generated simultaneously. Typical workflow is as shown below (Fig. 2).

It starts with finding out common points between all the images. Since, it uses images with large overlaps, lot of

Digital Elevation Model,
Fig. 2 SfM workflow (Iglhaut
 et al. 2019)

common features are available. The task of feature detection is usually achieved by employing SIFT (described in section “[Scale Invariant Feature Transform \(SIFT\)](#)”). Once the match points are available, relative pose between them can be estimated using Essential matrix (calibrated camera) and Fundamental matrix (uncalibrated camera).

Essential Matrix: This is based on coplanarity condition which relates same feature being imaged with two different views as expressed in Eq. (34).

$$x'^T E x'' = 0 \quad (34)$$

where x' and x'' are the image points in two different views.

$$E = RS$$

R is a rotation matrix and S is skew symmetric matrix,

$$S = \begin{bmatrix} 0 & -T_z & T_y \\ T_z & 0 & -T_x \\ T_y & T_x & 0 \end{bmatrix}$$

The essential matrix is of rank 2 and its two non-singular values are equal. Set of homogeneous Equations (38) can be solved using 5-point algorithm. Using the essential matrix, relative pose can be determined by doing its singular value decomposition. The pose is used to compute the 3D coordinates. Similar process can be used to determine 3D

coordinates for uncalibrated camera by determining Fundamental matrix. The model developed on sparse point cloud between consecutive images, obtained using SIFT, is first refined using the ground control points. Dense points are then computed in overlapping images by employing multi-view stereo image matching. Refined model parameters obtained previously are used for the dense point clouds to get accurate ground coordinates. These 3D point clouds can be interpolated to generate DEMs at required intervals by using any of the suitable DEM interpolation techniques described in section “[DEM Interpolation](#).”

Image Matching

Image matching is one of the most important steps in DEM generation. In this process conjugate points are usually generated automatically between pair of overlapping images acquired at different times. The density and accuracy of the conjugate points dictates the accuracy of resultant DEM. Major difficulties encountered in image matching are due to variable time of imaging and scale changes due to difference in imaging geometry. Two robust techniques are Hierarchical Image Matching (HIM) technique and matching using Scale Invariant Feature Transform (SIFT).

Hierarchical Image Matching (HIM)

HIM is a popular technique used for generating dense conjugate points (Kannan and Singh 2011). It consists of Condensation, Interest Point identification, Local Mapping and Image Matching. Condensation generates the sub-sampled images from the full resolution sets, creating pyramid layers of the images with varying resolution. Interest Point Operator identifies the high contrast points on the sub-sampled reference images for every layer. At the lower most level of the pyramid that is, most coarser resolution, image matching is done directly by extracting a window area of 16×16 from the reference image around the interest points and correlation is performed on a search area window 32×32 of the other image around the probable location. The image matching results of the previous level are used to map the probable location of interest points in reference image to their probable counterpart in the other image by means of Local Mapping. Thereafter Image matching is done on the locally mapped points. The steps involved in image matching are described below.

Image Condensation

Stereo images are acquired with different viewing geometry which includes different imaging times and view angles. This results in change in position of the same feature in both the images. This apparent displacement due to change in the position of feature is known as Parallax. Depending on viewing geometry and the height variations in the terrain, parallax may be observed in both x and y or in other words, across the track and along the track imaging directions. Undulations together with the stereo-imaging geometry of the satellite imaging system result in either the x-parallax or y-parallax

or both. During image condensation, the parallax magnitude is reduced by subsampling the images, usually by skipping the alternate pixels in across and along directions to have uniformity. This image condensation process results in formation of image pyramids at various subsampling levels. The position of the feature on the image is due to viewing geometry and the terrain undulation. The image condensation here attempts to reduce this displacement by means of skipping alternate pixel in both the directions for uniformity and generating a pyramid of subsampled images. Thus an image pyramid is generated by sub-sampling the image data. Each pyramid layer is referred to as Level. The point to be noted here is that though in each Level image is subsampled by skipping the alternate pixels and image breaks are created, HIM is capable of matching it accurately without significant loss of accuracy.

Interest Point Generation

Interest points are the points whose positions are well defined and can be determined accurately. Usually they are high contrast pixels, having high gray count variance with respect to their neighborhood pixels. Corners are a special case of interest point. Interest points are generated on one of the image only, in HIM which is treated as the reference image. One of the method for generation of interest point can be in the first step, screening of potential interest points by selecting the point whose gradients are above the predefined threshold with respect to the few neighborhood pixels and then in the second step filtering the screened candidates in first step using summation of gradients (IV) as weight for all points within the predefined window.

Comparison of gradients

Computation of Interest value gradients (IV)

(35)

where IV is the interest value, dg_i is the difference in the gray count of the interest point with respect to the i^{th} neighborhood pixel.

Local Mapping

The local mapping is used to estimate the location on the other image corresponding to every interest point on the reference image. A bivariate first- order polynomial is used for mapping

the interest points in the reference image to locations on other image.

$$X_r \rightarrow X_o = a_0 + a_1 * x + a_2 * y + a_3 * x' + a_4 * y'$$

$$Y_r \rightarrow Y_o = b_0 + b_1 * x + b_2 * y + b_3 * x' + b_4 * y' \quad (36)$$

where (X_r, Y_r) are the coordinates of the interest point in reference image, (X_o, Y_o) are the corresponding computed

Digital Elevation Model,
Fig. 3 Image matching process
 (Kannan and Singh 2011)

coordinates for the other image, (x, y) & (x', y') are the match point coordinates for the reference and other images respectively. In order to solve the above equations having 10 unknowns, the top 10 neighbourhood points are taken for computation. The process is also explained in figure below (Fig. 3).

Image Matching

Cross correlation technique is used to match between the reference and search window. A window Area (WA) is extracted from the reference image keeping (x, y) as the centre while, a search area (SA) window which is larger than WA for example of 32×32 pixels is extracted from other image keeping (x', y') as the centre. The positions of SA and WAs are taken from the local mapping file. The cross correlation coefficient between two windows search area s , and window area w of size $N \times N$ is defined as below:

$$R = \frac{\sum_{x=1}^N \sum_{y=1}^N s(x, y) w(x, y)}{\left[\sum_{x=1}^N \sum_{y=1}^N s(x, y)^2 \sum_{x=1}^N \sum_{y=1}^N w(x, y)^2 \right]^{\frac{1}{2}}} \quad (37)$$

Where $s(x, y)$ and $w(x, y)$ are pixel values at location (x, y) of s and w respectively. The correlation coefficient varies between 0 and 1 and the closer the value of R is to 1, the more similar the two windows are likely to be.

Scale Invariant Feature Transform (SIFT)

Scale invariant feature transform (SIFT) was introduced by David Lowe (2004) as a robust means for feature detection in an image. In this approach, identified features are invariant to image scaling and rotation. The features identified using SIFT are highly distinctive, reducing false matches due to occlusions and noise. SIFT has been used to extract features robustly for refining orientation parameters of the satellite (Neethinathan et al. 2013). The steps involved in feature generation are as follows:

Scale-Space Extrema Detection

In this step, candidate interest points are identified which are invariant to scale: stable across different scales. Entire image

Digital Elevation Model, Fig. 4 Computation of difference of Gaussians (DOG) of images for an octave

is searched for these features over different scales. It is implemented using Difference of Gaussian (DOG). DOG is obtained by subtracting the adjacent Gaussian images in the octave as shown in Fig. 4.

Lowe proposed to use scale-space extrema in DOG function convolved with the image, $D(x, y, \sigma)$, as the feature candidates. They are computed from the difference of two nearby scales separated by a constant multiplicative factor k :

$$D(x, y, \sigma) = (G(x, y, k\sigma) - G(x, y, \sigma)) * I(x, y) \quad (38)$$

where $*$ is the convolution operator, $I(x, y)$ is input image, and

$$G(x, y, \sigma) = \frac{1}{2\pi\sigma^2} e^{-(x^2+y^2)/2\sigma^2} \quad (39)$$

Keypoint Localization

In this step, the exact locations of the potential key points are determined by interpolation based on the stability measure. Brown and Lowe developed a method which uses Taylor's series expansion of the scale space function $D(x, y, \sigma)$ or $D(X)$ for fitting to get the interpolated location

of the maximum. The Taylor series expansion around the point X can be written as:

$$D(X) = D + \frac{\partial D^T}{\partial X} X + \frac{1}{2} X^T \frac{\partial^2 D}{\partial X^2 X} \quad (40)$$

The location of the extremum is determined by taking the derivative of this function with respect to X and setting it to zero. Apart from low contrast points, edges are also eliminated in this process, who have strong response in difference of Gaussian.

Orientation Assignment

In this process, based on local image gradients, orientations are assigned to each keypoint location. The keypoint descriptor is represented relative to this orientation. For assigning orientation to each key point, most prominent gradient orientation is identified using histogram. These steps provides invariance to orientation. The magnitude and orientation is computed by Eq. (41).

$$m(x, y) = \sqrt{(L(x+1, y) - L(x-1, y))^2 + (L(x, y+1) - L(x, y-1))^2}$$

$$\theta(x, y) = \tan^{-1}((L(x, y+1) - L(x, y-1)) / (L(x+1, y) - L(x-1, y))) \quad (41)$$

Keypoint Descriptor

In order to generate a distinctive feature descriptor from the keypoint and the orientation information, histograms are computed around the 16×16 region around the keypoint in a block of 4×4 . The histograms computed for these 16 blocks using 8 orientation bins are then stacked and normalized to form a 128-dimensional vector which serves as the feature descriptor for that keypoint.

DEM Interpolation

Conjugate points generated as part of image matching are irregularly spaced points. Hence elevation values computed for these conjugate points will form the irregular DEM. These values need to be interpolated at equally spaced intervals to make it amenable for various end user applications. Based on the accuracy requirements, either local or global fitting techniques can be applied for DEM interpolation. Few possible DEM interpolation algorithms are given below.

Weighted Average

This algorithm is based on the principle that within a neighborhood of a point with unknown z value, closer points gets

more weightage compared to the farther points. Therefore, the weights are assigned to all neighborhood points as an inverse Euclidian distance function. So, z -value at an unknown point can be interpolated using equations

$$z = \sum_{j=1}^n w_j z_j \quad (42)$$

where $\sum w_j = 1$ and $w_j = d(i, j)^{-2} / \sum d(i, j)^{-2}$

$d(i, j)$ is Euclidean distance between the point in question i and neighborhood point j , n is the number of neighborhood points.

The neighbor can be defined simply as the closest points in a circle defined around the point under consideration. Voronoi diagrams can aid in defining the neighborhood.

Polynomial Fitting

In this method, a polynomial is used to model a surface within a neighborhood region of a point for which z -value is to be interpolated. Normally, first, second, or third degree polynomials are used to generate a locally valid surface. The general form of a third degree polynomial is:

$$z = a_1 + a_2x + a_3y + a_4x^2 + a_5xy + a_6y^2 + a_7x^3 + a_8x^2y + a_9xy^2 + a_{10}y^3 \quad (43)$$

This polynomial can represent a surface with two extrema. For estimating z -value, minimum ten neighboring points are required. The discussion regarding the choice of neighbors is similar to that in previous section.

Finite Element Method

This method is also known as B-Spline interpolation. The characteristics of this interpolation method are that this method provides series of patches resulting in a surface that has continuous first and second derivatives. It ensures continuity in (a) z -value, as the surface has no cliffs; (b) slope, as slopes do not change abruptly; and (c) curvature, as a minimum curvature is achieved. For further details, refer Inoque (1986).

Kriging

Kriging is a statistical technique of estimation based on weighted average method. But the shape and size of the neighborhood window is determined from semi-variogram, which is constructed from the sample points (DeMers 1997). For every pair of points, its distance d and squared difference in z -values is calculated and a variogram is drawn with x -axis as d and y -axis as squared difference of z -values. As d increases, the squared difference also increases but it stabilizes after d attains a certain threshold value. Once the variogram has been developed, it is used to estimate distance weights for interpolation. Weights are

selected in such a way that the estimates are unbiased and the variation between repeated estimates is minimum.

Kriging uses the idea of regionalized variable, which varies from place to place with some apparent continuity but cannot be modeled with a single smooth mathematical equation. Kriging is an exact interpolator in the sense that the values interpolated will coincide with the data points at those locations.

Gerchberg Algorithm

This algorithm considers a regular grid, with holes (where elevations are unknown) as input, and computes the elevation for the entire grid by an iterative error-reduction algorithm based on constraints specified in spatial and frequency (Fourier) domains. Here, a regular grid is created with required output grid size, for the area specified by the user in terms of corner coordinates in easting and northing. Subsequently, the iterative error reduction algorithm is executed. Spatial constraint specifies that the resulting interpolated surface passes through all input points after each iteration. The frequency domain constraints dictate the frequencies present in the interpolated band-limited surface. By this approach, the total number of frequency components is made to be equal or less than the total number of input points (Chamy et al. 1994).

DEM Formats

DEM are available in following formats

- (a) Regular grid format where each point represents the planimetric coordinates and elevation over that. The grid intervals are chosen based on the resolution of input data, which does not degrade its accuracy during the process of interpolation.
- (b) Raster form in GeoTiff format where each pixel intensity value represents the elevation. Usually provided in UTM projection and WGS84 datum.
- (c) Triangulated Irregular Network (TIN): TIN overcomes the data redundancy in raster form for uniform region. The irregular points are stored in the form of triangles where no triangle consists of points from the circumcircle formed by these points. The irregularly spaced elevation values form the vertices of the triangle. Hence, TIN is a vector representation of the surface by a set of non-overlapping triangles using irregularly spaced elevation values. It is based on the principle of Delaunay triangulation (Richbourg and Stone 1997).
- (d) Contour Map: It is a map generated using contour lines where each line joins the points at equal height value. Each contour line is separated by a constant difference known as contour interval.

Summary

This chapter presents the mathematical techniques, required to model and determine the digital elevation model (DEM) or the three-dimensional coordinates of points on earth's surface (and hence the elevation above a reference ellipsoid). A generic statistical photogrammetric adjustment approach where all parameters, viz. camera model, platform position and orientation, image point pairs, and ground control points, are assigned appropriate weights and adjusted simultaneously is described. Details of coordinate transformations in case of satellite photogrammetry are presented. The Scale invariant feature transform (SIFT) is introduced as a support algorithm for generating DEM from digital frame images with very large overlap acquired by Unmanned Aerial Vehicles. Brief description of image matching algorithms used for finding homologous points in digital imagery is given.

The image processing techniques developed in Computer Science are finding more and more inroads in getting precise and dense DEM for the planet Earth. On the other hand, the techniques for determination of position and orientation of imaging camera, well developed in the discipline of Photogrammetry, are being used in simultaneous localization and mapping (SLAM) of autonomous devices.

Digital Filters

Gabor Korvin

Earth Science Department, King Fahd University of
Petroleum and Minerals, Dhahran, Kingdom of Saudi Arabia

Definition

In geoscientific signal processing, a *digital filter* is a system (usually a *time-invariant, linear operator* realized by a computer program) that performs mathematical operations on a *sampled, discrete-time* signal to reduce certain aspects and/or enhance certain other aspects of that signal. The term “*digital*” is meant in contrast with the other major type of filters, the *analog filter*, which is used during signal-recording and is typically realized by an electronic circuit operating on *continuous-time analog signals*.

Introduction

Because of space limitations, we can only discuss *linear, single-channel, convolutional, time-invariant filters*. For other kinds of filters, see, for example, Keating and Pinet (2011) (*nonlinear filters*); Meskó (1966) (*multichannel filters*); the Appendix and Shanks (1967) (*for recursive filters*); Scheuer and Oldenburg 1988 (*time-varying filters*). For the new-comer to digital filtering, the classic texts (Robinson and Treitel 1964, 1980) are still highly recommended.

Single-Channel Convolutional Filtering in Time Domain, the z-Transform

This kind of filtering is realized by *convolution*, which is a special case of *cross-correlation*. The convolution of $x(t)$ with $y(t)$, denoted by $x(t) * y(t)$ is the non-normalized *cross-correlation function* between $x(t)$ and the *time-reversed version* of $y(t)$: $x(t) * y(t) = \int_{-\infty}^{+\infty} x(t - \tau)y(\tau)d\tau$ (Eq. 1). Using *sampled data* $x_n = x(n \cdot \Delta t)$ as *input*, $f_k = f(k \cdot \Delta t)$, $k = 0, 1, \dots, M$ as *filter*, and $y_n = y(n \cdot \Delta t)$ as *output*, and approximating the integral with a finite summation, digital filtering is executed as $y_n = \sum_{k=0}^M x_{n-k}f_k$ (Eq. 2).

The *transfer characteristics* of filters (both digital and analog filters) are plotted in a particular form: The frequency is in logarithmic scale, and the attenuation of a given frequency is in linear scale, but in logarithmic (dB = decibel = $20 \cdot \log_{10} \text{Amplitude}_{\text{input}} / \text{Amplitude}_{\text{output}}$) units, as shown in Fig. 1. The slopes of the low- resp. high-cuts are specified in *dB/octave* where “octave” is the frequency range between f and $2f$ (where $f \rightarrow 0$ on the low-cut side, resp. $f \rightarrow \infty$ on the high-cut side). The “alias filter” (or “anti-alias filter”) is a special *analog high-cut filter* cutting out frequencies higher than $f_N (= f_{\text{Nyquist}}) = 1/(2 \cdot \Delta t)$ before sampling at equidistant discrete time instants $n \cdot \Delta t$.

Computationally there are many ways to execute filtering in time domain. Consider the simple example *Data* = {4, 2, 1, −1, 3, 5}; *Filter* = {2, 3, −2}; *Result* = ? We can directly use (a) the *convolution algorithm* (Eq.2); (b) the “moving paper-slip technique” (local *scalar product* of the data values with the filter values written on the moving slip, and note that the filter is written on the moving slip in reverse order).

$$\begin{array}{ccccccccc} & 4 & 2 & 1 & -1 & 3 & 5 & & \\ -2 & 3 & 2 & & & & & & \\ & 8 & & & & & & & \end{array}, \begin{array}{ccccccccc} & 4 & 2 & 1 & -1 & 3 & 5 & & \\ -2 & 3 & 2 & & & & & & \\ & 8 & 16 & & & & & & \end{array}, \dots;$$

(c) the “delay line technique: $2 \times \{4, 2, 1, -1, 3, 5, 0, 0, \dots\} + 3 \times \{0, 4, 2, 1, -1, 3, 5, \dots\} - 2 \times \{0, 0, 4, 2, 1, -1, 3, 5, 0, 0, \dots\} = \{8, 16, \dots\}$; but the most interesting and instructive way of filtering is (d) to form polynomials from the filter and the input data, and multiply them

Digital Filters, Fig. 1 Transfer functions for a set of *Ormsby-type bandpass filters* (Ormsby 1961), applied in *Seismic Data Processing*. These filters are specified by their four corner frequencies corresponding to the $-6, 0, -6$ dB points, respectively. (Recall that “ -6 dB” means signal attenuation by a factor 0.5.)

as polynomials of the variable z : $(4 + 2z + z^2 - z^3 + 3z^4 + 5z^5) \cdot (2 + 3z - 2z^2) = 8 + 16z + \dots$.

The transform $Z\{a_n\}: \{a_0, a_1, \dots, a_n\} \rightarrow a_0 + a_1z + \dots + a_nz^n$ (Eq.3) transforming sequences to polynomials is called *z-transform*. Its most important property relates to digital convolution: If $Z\{a_n\} = A(z)$; $Z\{b_n\} = B(z)$, then $Z[\{a_n\} * \{b_n\}] = A(z) \cdot B(z)$ (Eq. 4).

Filtering in Fourier Domain

In digital filtering, the use of the Fourier method is based on the *Convolution Theorem*. Denote the *Fourier transform* of $x(t)$ as function of frequency f by $F[x(t); f] = \int_{-\infty}^{\infty} x(t)e^{-i2\pi ft} dt = X(f)$ (Eq.5) where $i = (\text{in engineering applications sometimes denoted by } j) \sqrt{-1}$. Then (if all Fourier transforms exist) the *Convolution Theorem* states that, for all frequencies, $F[x(t) * y(t)] = X(f) \cdot Y(f)$ (Eq. 6). A particularly fast DFT (*Discrete Fourier Transform*, or *Digital Fourier Transform*) algorithm is the *Fast Fourier Transform* (FFT, discovered by Cooley and Tukey 1965). The FFT is only applicable if the data and the filter have the same length, and the number of data is a high integer power of 2. In practice, the FFT is computed in the following standard

steps: (a) Pad out the data with zeros to obtain a series of length $N^* > N$ where N^* is a power of 2; (b) *taper* (“truncate”) the series of data at its beginning and end; (c) do the same with the series of filter coefficients; (d) use FFT to get the Fourier Transforms of the padded and tapered data and filter. Filtering is then done by multiplying the two Fourier Transforms, and then inverse Fourier Transforming back to time domain. “Tapering” or “truncating” of the data is a critical part of the procedure, and many ways are available in most data-processing software packages to do it. Conventional truncation “windows” are (a) the *rectangular window* or *boxcar function*.

$$W(L) = \begin{cases} 1 & |L| \leq L_m \\ 0 & \text{otherwise} \end{cases} : \quad \text{(b) the Bartlett window}$$

$$W(L) = \begin{cases} 1 - \frac{|L|}{L_m} & |L| \leq L_m \\ 0 & \text{otherwise} \end{cases} : \quad \text{(c) the Hannning window}$$

$$W(L) = \begin{cases} 0.5 + 0.5 \cos \frac{\pi L}{L_m} & |L| \leq L_m \\ 0 & \text{otherwise} \end{cases} : \quad \text{(d) the Hamming window}$$

$$W(L) = \begin{cases} 0.54 + 0.46 \cos \frac{\pi L}{L_m} & |L| \leq L_m \\ 0 & \text{otherwise} \end{cases} : \quad \text{and (e) the Parzen Window}$$

(note that it has a polynomial equation, not trigonometric!)

$$W(L) = \begin{cases} 1 - 6\left(\frac{L}{L_m}\right)^2 + 6\left(\frac{L}{L_m}\right)^3 & |L| \leq 0.5L_m \\ 2\left[1 - \left(\frac{L}{L_m}\right)^3\right]^2 & 0.5L_m \leq |L| \leq L_m \\ 0 & |L| > L_m \end{cases} \quad \text{(Eqs. 7–11).}$$

Transfer Function of Digital Filters

If F is a time-invariant linear system (“filter”), its *transfer function* (TF) for the circular frequency $\omega = 2\pi f$ is defined as $T(\omega) = \frac{\text{output}}{\text{input}} = \frac{F\{e^{j\omega t}\}}{e^{j\omega t}}$ (Eq. 12).

We shall apply this rule, making use of the linearity of F , to compute the transfer function of the digital filter $F = a_0 + a_1 z + \dots + a_n z^n$. We find that the transfer function of the filter can be obtained by substituting $z = e^{-j\omega \cdot \Delta t}$ (where Δt is the sampling interval) into the z -transform of the filter; that is, we have $T(\omega) = a_0 + a_1 e^{-j\omega \cdot \Delta t} + \dots + a_n e^{-j\omega \cdot \Delta t}$ (Eq. 13). The TF (13) is complex-valued, its absolute value is $|T(\omega)| = \sqrt{\sum_{k=0}^n \sum_{l=0}^n \cos[(k-l)\omega \cdot \Delta t]}$ (Eq. 14, the expression below the square root sign is positive semi-definite!).

We usually design the frequency filters in the *Fourier Domain*, get the *weight function* (or *response function*) of the filter by *inverse Fourier Transform*, and finally sample and truncate the result for practical use.

The main problem encountered in digital filter design is caused by the *Gibbs Phenomenon* (an unavoidable oscillatory overshoot of the Fourier series of a function occurring at jumps and non-differentiable discontinuities). Because of this effect, the transfer function of the *sampled and truncated* filter response function will be not exactly equal to the desired and carefully designed theoretical transfer function. The minimization of this error is a main task of modern digital filter design (Meyerhoff 1968).

A filter with very good properties, widely used in *Seismic Data Processing*, is the *Ormsby Filter* (Ormsby 1961). Its transfer function has a trapezoidal shape. In the simplest case, the Ormsby LP (*Low Pass*) filter’s transfer function is given mathematically as

$$H_1(\omega) = \begin{cases} 1 & \text{for } |\omega| \leq \Omega_1 \\ 0 & \text{for } |\omega| > \Omega_2 \\ (\omega + \Omega_2)/\Delta\Omega & \text{for } -\Omega_2 \leq \omega < -\Omega_1 \\ (\Omega_2 - \omega)/\Delta\Omega & \text{for } \Omega_1 \leq \omega \leq \Omega_2 \end{cases}$$

(Eq. 15a, $\Delta\Omega = \Omega_2 - \Omega_1$).

Inverse Fourier Transform and some simple mathematics yield this filter’s response in time-domain:

$$h_1(t) = \frac{1}{\pi t} \sin \frac{(\Omega_1 + \Omega_2)t}{2} \times \frac{1}{\pi t \cdot \Delta\Omega} \sin \frac{t \cdot \Delta\Omega}{2} = \frac{\cos \Omega_1 t - \cos \Omega_2 t}{2\pi^2 t^2 \cdot \Delta\Omega}$$

(Eq. 15b, for $t = 0$ the expression should be computed by l’Hôpital’s rule). As seen in Fig. 1, Ormsby BP (*bandpass*) filters are specified by four numbers, namely the four “corner frequencies” f_1, f_2, f_3, f_4 corresponding to the $-6, 0, 0, -6$ dB points, respectively. (Recall that -6 dB corresponds to an amplitude attenuation by a factor 0.5.)

Time Varying Filtering (TVF, see Scheuer and Oldenburg 1988). Different BP filters emphasize different phenomena and patterns on the observed record. In many cases we need to apply different BP filters to different parts (sections) of the record. First we make a *filter analysis* to see which is the best

filter for a given section. We cannot introduce *abrupt changes* between two consecutive filters, because this would create an artificial, geologically meaningless, false “boundary.” Rather, we prefer to make slow, *gradual changes* by applying a *ramp* of reasonable length centered at the time instants of filter change.

Single-Channel Optimal Filters

Basic equation of optimal filtering: Suppose we have a stationary time-series $x = \{\dots, x_{n-1}, x_n, x_{n+1}, \dots\}$ and we would like to transform it as *closely as possible* (in the $\text{RMS} = \text{Root Mean Square error norm}$) into some *desired* time series $d = \{\dots, d_{n-1}, d_n, d_{n+1}, \dots\}$ by means of *convolving it with a filter* $= \{\sigma_0, \sigma_1, \dots, \sigma_M\}$. The problem of finding the *optimal filter* was solved by Norbert Wiener in the 1940s for *smoothing, interpolating, and predicting stationary time series* (Levinson 1947). If the input $x = \{\dots, x_{n-1}, x_n, x_{n+1}, \dots\}$ and the desired output $d = \{\dots, d_{n-1}, d_n, d_{n+1}, \dots\}$ are *stationary random sequences*, then the coefficients $\{\sigma_0, \sigma_1, \dots, \sigma_M\}$ of the optimal filter can be found from the linear system of equations:

$$\begin{pmatrix} R(0) & R(1) & R(2) & \dots & R(M) \\ R(1) & R(0) & R(1) & \dots & R(M-1) \\ R(2) & R(1) & R(0) & \dots & R(M-2) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ R(M) & R(M-1) & R(M-2) & \dots & R(0) \end{pmatrix} \begin{pmatrix} \sigma_0 \\ \sigma_1 \\ \sigma_2 \\ \vdots \\ \sigma_M \end{pmatrix} = \begin{pmatrix} R_{dx}(0) \\ R_{dx}(1) \\ R_{dx}(2) \\ \vdots \\ R_{dx}(M) \end{pmatrix}$$

(Eq. 16, all arguments of the correlation functions are in units of the sampling time Δt), where $R(k) = R_{xx}(k)$ is the *ACF* (*Autocorrelation Function*) of $\{x_n\}$, $R_{dx}(k)$ is the *cross-correlation function* between the desired output $\{d_n\}$ and the input $\{x_n\}$ at lag k . This is a very large system of equations (in general the matrix has some 50×50 elements or more). Because of the special symmetries of the *Autocorrelation Matrix* (it is a so-called *diagonal-constant “Toeplitz matrix”*) the system of equations can be solved very efficiently by using Levinson’s algorithm (Levinson 1947), but it should be kept in mind that the system is strongly *ill-conditioned*.

A frequently occurring case when we use optimal filtering is the *Prediction of Stationary Time Series* (e.g., the so-called *predictive deconvolution* in *Seismic Data Processing*, see Robinson and Treitel 1980). Suppose we observe a random time series $x(t)$ and want to optimally *predict* (in the sense of minimal *Root Mean Square error*) its future value a time τ ahead, that is $x(t + \tau)$. If a convolutional filter of length $M + 1$ is used for this purpose, that is when we predict for a time τ ahead in the form $x(t + \tau) \approx \sum_{k=0}^M \sigma_k x(t - k)$ (Eq. 17), the optimum prediction filter coefficients should satisfy the equation:

$$\begin{pmatrix} R(0) & R(1) & R(2) & \cdots & R(M) \\ R(1) & R(0) & R(1) & \cdots & R(M-1) \\ R(2) & R(1) & R(0) & \cdots & R(M-2) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ R(M) & R(M-1) & R(M-2) & \cdots & R(0) \end{pmatrix} \begin{pmatrix} \sigma_0 \\ \sigma_1 \\ \rho_2 \\ \vdots \\ \sigma_M \end{pmatrix} = \begin{pmatrix} R(k) \\ R(k+1) \\ R(k+2) \\ \vdots \\ R(k+M) \end{pmatrix} \quad (\text{Eq. 18}).$$

Appendix: Recursive Filtering (Shanks, 1967)

In *convolutional filtering*, the output $\{y_n\}$ only depends on the input $\{x_n\}$, $y_n = \sum_{k=0}^M x_{n-k} f_k$ (Eq. 2). In a more general filtering scheme, the output might also depend on some of its own previous values. For example if y satisfies a *difference equation* of the form

$\sum_{k=0}^N a_k y_{n-k} = \sum_{k=0}^M b_k x_{n-k}$ (Eq. 19) where $a_0 \neq 0$, this equation can be changed to the equation of *recursive filtering* (Shanks 1967) $y_n = \sum_{k=1}^M \alpha_k y_{n-k} - \sum_{k=0}^N \beta_k x_{n-k}$ (Eq. 20). The *transfer function* of such a recursive system is described by

$$R(\omega) = \frac{\sum_{k=0}^M \beta_k \exp[-ik\omega \cdot \Delta t]}{1 + \sum_{k=1}^N \alpha_k \exp[-ik\omega \cdot \Delta t]} \quad (\text{Eq. 21}).$$

This form of the transfer function is especially suited for the *zero- and pole design* of digital filters to achieve favorable filtering properties.

Concluding Remarks on the Use of Digital Filtering

We briefly discussed digital filters used in Geosciences, concentrating on *single-channel convolutional filters*. Finally, we want to add a few words of warning concerning their use. It has been proved in *Information Theory* that the application of any kind of linear systems, such as a digital filter, to an observed signal inevitably causes *loss of information* about the signal, that is it would lead to a less precise *geologic interpretation*. If a filtered record is used as input to some *inverse problem* (inverse problems are notoriously *ill-conditioned*, and sensitive to small changes in their input), one might even “detect” spurious geologic anomalies. Anybody who uses filtered data for geologic interpretation should carefully check the reality of the results obtained against the original, unfiltered data.

Digital Geological Mapping

Chengbin Wang¹ and Xiaogang Ma²

¹State Key Laboratory of Geological Processes and Mineral Resources & School of Earth Resources, China University of Geosciences, Wuhan, China

²Department of Computer Science, University of Idaho, Moscow, ID, USA

Definition

Digital geological mapping is to use the portable digital equipment to collect first-hand geological features information by imitating the process of field geological mapping of geologists. The collected information is further processed to make digital geological maps and databases for sharing.

The History of Digital Geological Mapping

Initiatives of digital geological mapping started in the 1980s. Some geological codes and principles were designed to standardize field data collection for producing digital geological map and database (Wright and Stewart 1990). Along with the fast development of portable equipment, GPS and GIS, computer scientists and geologists tried to develop the software to support the field data collection and replace the traditional paper-based geological mapping method. Fieldlog, a software system of digital geological mapping developed by the Geological Survey of Canada, was released in 1991 (Brodaric 1992, 2004). Subsequently, a series of digital geological mapping software systems were developed and tested in the geological mapping in the Europe, Australian, China, and North America, for instance, ArcPad-ArcGIS system (Pavlis et al. 2010), GSMCAD FieldPad (Williams et al. 1996), MapIT (Blewett and Hazell 1997; Brown and Sprinkel 2008; De Donatis 2007), GeoMapper (PenMap) (Brimhall and Vanegas 2001), FieldBook (Briner et al. 1999), Natmap (Broome et al. 1993), SIGMA system (Jordan and Napier 2016), GeoSurvey (Liu et al. 2001), FieldMove (Lundmark et al. 2020; Senger and Nordmo 2020), StraboSpot (Walker et al. 2019), and DGSS-RGMAP (Li 2011; Li et al. 2008a).

Digital Geological Mapping System

The realization of an efficient digital geological mapping system depends on the development of hardware and software. The digital geological mapping system can be divided into three modules: field data acquisition module, field data cleaning module, and mapping and database module. The field data acquisition module is a portable equipment (e.g., personal digital assistant (PDA), tablet PC, and smart phone) with data acquisition software, camera, GPS, and digital compass. Geologists use the field data acquisition module to collect as much geological feature information as possible, such as attitude, geological boundary, contact relationship of geological bodies, photo, geological sketch, and text description.

The functions of field data cleaning module are to collate geological data collected in the field. Due to the complexity of the field environment, the first-hand geometry and attributes of geological features are semifinished products with irregular shapes and missing or incorrect attribute information. These shortcomings need to be addressed using the field data cleaning module. This module is a special GIS platform for indoor use, which can be an extension tool of secondary development based on the existing GIS platform or an independent GIS tool. The role of mapping and database module is to integrate the cleaned field data to produce the geological map and geological dataset for sharing in a GIS environment.

In the three modules, the biggest challenge is to design a data model in the field data acquisition module for easy operation by geologists in the field and further processing indoor to produce the geological map and database. It is necessary to reach a balance between the complex field environment, limited power supply and screen size, and easy post-processing requirements. Keep it simple stupid is a critical rule for the design of the data model. The point and polyline are preference for data input in the field. Recently, China Geological Survey provided a solution of PRB data framework to imitate the process of data collection in the geological mapping (Li et al. 2008b). As a whole, the PRB model constitutes a data framework for geological mapping. Other information such as sample, attitude, fossil, photo, and sketch can be added nearby and attached to the corresponding PRB element using its ID number.

The Process of Digital Geological Mapping

The workflow of digital geological mapping can be divided into the following steps:

1. Prepare the reference base map of remote sensing imagery, topographic map, and small-scale geological map for geological data collection in the field.
2. Design a geological survey route based on the base map.
3. Geological data collection in the field using portable equipment (e.g., smartphone, PDA, tablet PC, iPad).
4. Cleaning and modification of first-hand geological data indoors.
5. Integrate geological survey data and build a raw data database.
6. Draw the geological map and built a geological database for sharing.

Summary

In traditional geological mapping, a toolbox, including pencil, compass, camera, hammer, magnifying glass, notebook, GPS receiver, and sketch paper is used to collect field geological data. The small size portable equipment replaces the roles of paper, pencil, compass, camera, notebook, and GPS receiver and provides an easy and integrated way to collect geological feature information. Field data collection is not the end of digital geological mapping. The digital geological mapping system also revolutionizes the mapping workflow and can be used to produce digital geological maps and databases for sharing and further use. The development of big data, artificial intelligence, and cloud computation also promotes the transformation from digital geological mapping to smart geological survey, which in turn will lead to many research topics of interest in mathematical geoscience and geoinformatics.

Digital Twins of the Earth

Stefano Nativi and Max Craglia
European Commission –Joint Research Centre (JRC), Ispra, Italy

Synonyms

Earth Digital Twins

Other terms sometimes used with a similar meaning are: City Twins; Digital Earth; Local Digital Twins

Definition

A Digital Twin of the Earth is the digital replica of an Earth system component, structure, process, or phenomenon obtained by merging digital modelling (notably, learning-based models) and real-world observational continuity – that is, natural and societal sensing data streams.

A Digital Twin of the Earth continuously learns and updates itself and must be seen as a living digital simulation model that modifies and changes itself as its physical counterpart changes.

Essential Concepts and Components

Digital Twin (DT) paradigm and systems have been around for decades in the industrial manufacturing processes. However, it is only with the recent advent of transformative digital technologies and the datafication of society that the DTs paradigm has been more and more applied in the geoscience domain. Empowered by the Internet of Things and AI technologies, the DT model provides the most advanced pattern to generate that intelligence required by decision makers, through the development of cyber-physical systems (Jacoby and Usländer 2020).

In geoscience, DTs of the Earth aim to effectively simulate and predict the behavior of key natural and societal systems/

Disclaimer: The views expressed are purely those of the authors and may not in any circumstances be regarded as stating an official position of the European Commission.

Digital Twins of the Earth,

Fig. 1 The cyber-physical model characterizing a Digital Twin of the Earth

processes/phenomena by leveraging the huge amount of data generated and shared daily on the network, along with the advancement in AI technology. For scientific experts and policy makers, DTs of the Earth are extremely advanced instruments providing a digital replica of important natural and social phenomena and processes (characterizing our planet), the understanding of which is essential to realize a “smart” and more sustainable society. They can be therefore important instruments contributing to implement the UN Sustainable Development Goals (SDGs) agenda and the European Green Deal transition.

By connecting the physical and the virtual worlds, data is transmitted seamlessly from one to another allowing the virtual entity to exist simultaneously and interact with the physical entity. On the other hand, the DT concept permits to decouple the digital replica from its physical entity, making it easier to change it and run fast and safe simulations. Utilizing advanced data-driven analytical procedures, it is possible to generate those insights that could not be carried out using the traditional observation models.

As depicted in Fig. 1, a DT of the Earth includes three main components: the *Physical Entity*, its *Digital Representation*, and the *Connection* channel between the two (Nativi et al. 2020). The main interaction features characterizing a DT are (Jones et al. 2020; ISO TC184 2020): interoperability, information model, data exchange, administration, synchronization, and push mode (i.e., publish and subscribe model). Therefore, the cyber-physical model characterizing a DT of the Earth is cyclical and commonly distinguishes the following set of phases and related activities:

1. Policy operationalization phase: to recognize the Earth entity (i.e., system/process/phenomenon) important to address a given societal or policy need
2. Observation and datafication phase: to continuously observe the acknowledged Earth entity, generating one or more data streams
3. Modelling phase: to utilize the data stream(s) for training and/or ingesting the digital representation (model) of the observed physical entity

4. Analytical phase: to utilize the digital model for generating simulations and/or predictions
5. Actionable intelligence phase: to interpret the generated insights and act-back on the observed Earth entity

DT Versus Digital Model

It is useful to distinguish DTs from the “digital model” concept that is often used with an equal meaning. The two concepts implement different levels of integration between the physical and digital entities (Kritzinger et al. 2018). In particular, a digital model does not implement any form of automated data exchange between the physical and the digital entities (e.g., in Fig. 1, the “Data stream” connection channel is off-line).

Some Significant Research and Innovation Applications

According to a recent survey conducted by the Joint Research Centre (JRC) of the European Commission for the EU Destination Earth initiative (Nativi et al. 2020), the DT of the Earth paradigm has been utilized in several projects and initiatives. The survey collected information from online publications, EU research and innovation frameworks, international initiatives, and a set of the elicited experts – for example, GEO (the intergovernmental Group on Earth Observation) (<https://earthobservations.org/>) experts. Table 1 is generated from this survey, reporting some significant research and innovation applications (categorized by area) that build on the concept of Digital Twins of the Earth. Naturally, the list of projects and initiatives is far from being exhaustive, its aim is to provide an idea of the application domains diversity and the lively activity concerning Digital Twins of the Earth. As shown, the earth system modelling and smart cities are the two most prominent domains.

Current Investigations, Controversies, and Gaps in Current Knowledge

The DT of the Earth model represents a key instrument for developing the Digital Earth vision (ISDE Council 2012). For this reason, the two terms quite often are used

interchangeably. In addition, it constitutes a significant archetype and reference framework for introducing a new scientific discipline (a subdiscipline of Data science) that was introduced by Guo et al. (2020) and called Big Earth Data science.

To embrace the philosophy characterizing the DTs of the Earth, it is important to adopt a truly distributed and digital

Digital Twins of the Earth, Fig. 2 Digital Twins as a key instrument to leverage digital transformation of society for its sustainability and resilience

approach (see the “Digital Ecosystem”) in which data and models are accessible online and are interoperable in a computing and storage environment that provides scalability for the different applications – for example, via edge, containerization, and cloud computing. For the modelling and analytical software, that requires to move progressively from a tool-oriented approach (where access to models is provided via a software tool requiring human interaction) to a service-oriented approach (where machine-to-machine automatically interact through network services and APIs), and ultimately resource-oriented approach (where the code implementing the model is moved and run where the processed big data and the required computing scalability are located) (Nativi et al. 2021). Tao and Qi (2019) argue that the Geosciences academia and research community need to investigate further the following issues:

- Improved modeling techniques -further focusing on data-driven analytical techniques, in addition to the more traditional process-driven ones
- (Big) data streams optimization and their interoperability with modelling platforms – for example, by unifying data and model standards
- Design and implementation of innovative processes to implement and manage DTs of the Earth systems – that is, the DT of the Earth reference framework engineering

According to the scale (and type) of the Earth entity replicated digitally, a given DT can be defined as global, national, regional, or local. Smart cities (aka urban DTs) represent a popular example of local DT (Deng et al. 2021).

In 2019, ISO JTC1 (Information Technology) created an Advisory Group to recognize the standardization landscape, the possible existing gaps, and eventually recommend the creation of Systems Integration entity in the form of a new Subcommittee on Digital Twins.

Summary or Conclusions

The digital transformation of society underpins the development of a cyber-physical world that could prove essential in making human development sustainable and thus save the planet. Digital Twins of the Earth are instrumental in connecting the physical and virtual realms and in generating the knowledge required to minimize the impact of our society on the Earth – as depicted in Fig. 2. The DT of Earth systems represent Earth entities (components, processes, or phenomena) to capture their behavior over time, allow to run simulations, and generate actionable intelligence. For these reasons, there are already many research and innovation projects worldwide as well as initiatives applying the DT of Earth paradigm. The DTs of the Earth paradigm differ from the more traditional digital models because of the full synchronization of the digital representation with the Earth entity. Therefore, a DT of the Earth is a living digital simulation model that modifies and changes itself as its Earth counterpart changes. This important characteristic raises several challenges to the scientific and engineering communities.

Dimensionless Measures

Ekta Baranwal

Department of Civil Engineering, Jamia Millia Islamia, New Delhi, India

Synonyms

Bare quantities; Pure quantities; Scalar quantities

* Words, ‘quantities’ and ‘metrics’ are the synonyms of ‘measures.’

Definition

Dimensionless measures are those quantities that do not have any physical dimension or are considered to have only one dimension. When any measure is derived from being independent of concurrent variations in the fundamental quantities chosen to derive it, then the derived quantity is dimensionless. These measures are part of “dimensional analysis” used in various fields like science, mathematics, engineering, and economics.

Introduction

Since the nature of the objects and features we see on the earth is three-dimensional. There is a general and universal acceptance that the geospatial data should be acquired and analyzed through methods that aim to examine and explore the features on the globe in three dimensions. But the question arises here “is it justified for doing so?”. Though, in a Penrose conference in 2006, i.e., “Unlocking 3-D Earth Systems—Harnessing New Digital Technologies to Revolutionize Multiscale Geologic Models Durham University, Durham, UK, 17–21 September 2006,” participants discussed understanding the

dimension, uncertainty magnitudes, and managing various types of geoscience datasets. Inspired by this conference, some of the participants produced a better understanding of dimensionality for geospatial or Geoscience data illustrating it as “Describing the dimensionality of geospatial data in the earth sciences—Recommendations for nomenclature” (Jones et al. 2008). According to them, “the dimensionality of an object is independent of whether the object’s location in space is known” (Jones et al. 2008). Therefore, dimensionality can be defined precisely in many ways in mathematics, but there are also varied definitions in science and engineering. For a clear understanding, we must know that mathematically, according to Euclidean geometry, the topological dimension of a single point is zero, for line or curve one, for plane or surface two, and for the volume is three. Hence, there is no dependency of the object’s dimension upon its spatial location through this aspect, i.e., representation of any object with its known attribute values in a coordinate system does not fluctuate its Euclidean dimension.

But in general scientific practice, the dimensionality of an object is considered the synonym of coordinate axes used to represent the position of that object in space. This approach is also widely accepted in earth science to define the dimensionality of geoscience data, for example, for developing maps and photographs of the earth’s surface using geoidal, cartesian, and cylindrical coordinate systems, each having three coordinate axes. Also, this practice is beneficial while transforming the representation of an object’s coordinate system into another coordinate system. Since a coordinate system is utterly capricious and random, the transformation of coordinate systems does not affect the dimension of the object while mapping its position in various coordinate systems. So, in brief, portraying the geoscience data in a particular coordinate system with three parameters or axes represents its dimensionality. This viewpoint leads towards the utilization of dimensional analysis for geospatial or geoscience data, i.e., dimensional analysis can be appropriate in geoscience and related fields.

Dimensional analysis is a mathematical operation and a part of mathematical modeling used to study and understand the nature of objects. It provides the relationship between two or more physical quantities through dimensions and measurement units. Many methods are used to obtain this relation for various applications in *physics, chemistry, mathematics, statistics, engineering, and economics*. Unit conversion and determining the preciseness of the equations are the primary and most common utilization of dimensional analysis. In mathematics, this unit conversion is done through a conversion factor considering no change in the relative amount. Performing the conversion factor requires building a ratio or fraction that equals value one. This developed ratio or fraction with value one is one of the quantities from dimensionless measures. Therefore, dimensionless quantities or measures are an essential part of dimensional analysis. There are several

methods used in Geoscience for analyzing geospatial data through landscape metrics, geospatial metrics, spatial statistics, and temporal and spatiotemporal metrics (Bhatti et al. 2018) like fractal dimension for determining the number of patches; various indices to know about the patch density, richness, shape, diversity, variation, distance, connectivity; integration, correlation, regression, interpolation, and many more mathematical and statistical operations are used in geoscience.

In geoscience, remote sensing images or raster data are widely used to get spatial information through various analyses. Of course, these analyses are based on several mathematical operations. Since the images and raster data form a matrix, their dimensional analysis and mapping are done through the mathematical operations of the dimension matrix. Dimension matrix, in this case, represents the spatial entities in images with unitless pixels. Details of the dimension matrix and dimensionless quantities can be referred to (Tiihonen 2016). Therefore, this geoscience dataset provides many possible dimensional and dimensionless metrics. Among the several measures used in geoscience, some dimensionless measures play a significant role by providing the base to geoscience data and analyzing it like the coefficient of determination, coefficient of variation, correlation, Euler's number, f-number (scale), pixel, Poisson's ratio, radian measure, Rayleigh number, refractive index, relative density, relative permeability, relative permittivity, transmittance, accuracy assessment, Kappa coefficient, spectral index, and goodness of fit. Given the above explanation of ratio, which is a dimensionless quantity used in many forms in geoscience, for example, scale is a ratio and a dimensionless metric that is a widespread, basic, but essential term used in geoscience either we talk about geoinformatics, geospatial information system (GIS), remote sensing, surveying, or photogrammetry. In the below sections, we will see the exploration of few dimensionless quantities widely used in Geoscience.

Dimensionless Measures in Geoscience

In geoscience, numerous metrics are used that belong to dimensionless quantities. For example, refractive index, Rayleigh number, radian measure, relative density, relative permeability, relative permittivity, transmittance, and Poisson's ratio are utilized in remote sensing fundamentals because the principles of remote sensing lie on the footprint of physics and optics. Most of these metrics are part of how various sensors transform electromagnetic radiation from features into signals and images. After that, pixel and scale are the dimensionless quantities used for images in remote sensing and photogrammetry. In GIS, scale is used for both vector and raster data, while the pixel is the metric for raster data. Pixels and scale, both measures, are the core in geoscience because experts can

identify and analyze the earth's surface features through these quantities. Apart from this, several indices were developed to study and extract the information from geospatial datasets, whether it is about land use land cover (LULC), spatiotemporal assessment of an object and area, dynamic changes in biophysical components and fauna and flora, or the assessment and management of various needs and services we are using in our daily lives. For making any decision, assessed and analyzed data of remote sensing and GIS are also validated with ground truth data or highly accurate detailed data. This validation is performed through the accuracy assessment methods, where again some dimensionless metrics are used in the process. Below are some examples to study and understand the role of some dimensionless measures in Geoscience that can also be found in other articles given in the cross-reference section.

Example 1: Pixel and Pixel Value

Photographs and images are two-dimensional representations of our three-dimensional world developed through an array of discrete picture elements. These picture elements are known as pixels which is the smallest and dimensionless measure of an image. Several pixels are arranged in rows and columns to form a photograph. Remote sensing images are the product of electromagnetic radiance of the features of the earth's surface. Therefore, each pixel in these images carries the radiance value, also called the brightness value (BV) (Fig. 1). Since images are digital, the pixel value is also known as a digital number (DN). Pixels in the image and its DN, both measures of a photograph, are dimensionless quantities. Pixel provides the minor information in an image that is considered the single unit element and an image sample. The DN in a pixel ranges from 0 to $2^n - 1$ according to the image's radiometric resolution (e.g., 8-bit, 16-bit, or 32-bit), which is also unitless or dimensionless and used in a variation of color tones in monochromatic and multispectral images. These pixel values and the color of pixels are used for all the quantitative and qualitative calculations in image processing to retrieve numerous information. Of course, the number of pixels varies in an image based on its spatial resolution and the scale on that image and the details of the information it contains.

Example 2: Scale

Scale is one of the essential elements in geoscience datasets, whether it is a photograph in remote sensing and photogrammetry or one kind of map in GIS. Scale is a ratio to represent the coverage area of the ground on an image or map. In other words, the scale represents the globe's features into a two-dimensional image or map or a simulated three-dimensional model, and therefore it is one of the characteristics of image and maps. Scale can be defined differently in various fields, and it is the base behind information details of covered ground area. Details about the features and objects present on a map

Row	0	1	2	3	4	5	6

Dimensionless Measures, Fig. 1 16-bit Landsat OLI/TIRS image and some of its pixel values

are directly related to the scale of that map. “Scale is the ratio between the distances measured on the map and the corresponding distances measured on the ground” (Lo and Yeung 2007). Scale can be represented in fraction, statement, or linear graph and generally categorized as large-scale, medium-scale, and small-scale. This concept of scale is also for the scale of an image. Scale is directly proportional to the details on the map and image about features of the earth’s surface and their spatial resolution but inversely proportional to the ground coverage area. That means a larger-scale map and image have high spatial resolution and detail information about the scene because it covers a small portion of the ground like a map of a single ward of a city and images captured through drones for a small area. The large-scale map and images can distinguish between the most miniature objects, shapes, and boundaries.

On the other hand, small-scale maps and images do not provide minor details about features. However, they cover a large ground area with many objects and features and depict only major ones like highways, airports, rivers, general vegetated areas, and built-up areas. Map and images of medium-scale cover a geographic area relatively larger than large-scale and smaller than small-scale with details that lie in between the both like covering the minor roads, footbridges, differentiate between forest and agricultural land. Scale is a ratio, therefore a dimensionless metric in geoscience but of great importance. The scale of map or image is often about the spatial scale, but geoscience also uses the time scale (temporal scale), which is used to study and understand the changes on the earth’s surface. The temporal scale depends on how frequently the geospatial data is acquired. The higher the data collecting frequency, the higher the temporal resolution of the geospatial data and its temporal scale. Therefore, any

geospatial data’s scale (spatial and temporal) is one of the bases in any application. Even in an image, the number and size of pixels are based on the scale of that image. It again decides the density of information present in that image. Scale is also used for map projections, measuring the distortions while projecting the map, for geometric transformation, editing and analysis of geospatial data (Chang 2008). In Fig. 2, it is seen the difference between a medium and high-scale image, i.e., medium-scale image is only able to differentiate built-ups, river, and vegetation in gray, blue, and green color, respectively (Fig. 2, left). In contrast, individual entities can be identified through high-scale images like roads, rooftops of each house, tree canopies, and even bikes on the road (Fig. 2, right).

Example 3: Contrast Ratio (CR)

It is the ratio of brightest and darkest pixels of the image used to detect and resolve the objects by distinguishing the brightness value of the pixels (Sabins 2000). The ratio is represented as:

$$CR = \frac{B_{\max}}{B_{\min}}$$

where $B_{\max}$ is the maximum brightness value in the image and $B_{\min}$ is the minimum brightness value. CR provides the brightness profile in the scene, which is helpful to differentiate the objects and background in the image. CR is much beneficial for object detection through a monochrome or panchromatic image. Here, brightness values (pixel value) and CR (ratio of two dimensionless quantities), all measures are dimensionless.

Dimensionless Measures, Fig. 2 Medium-scale and resolution image (left) and high-scale and resolution image (right)

Example 4: Spectral Index or Band Ratio

Band ratio is similar to CR in detecting and highlighting features but through a multispectral image. Here, multiple spectral bands are used to form a ratio to extract features. Therefore, it is also known as spectral ratio and spectral index because it measures the changes between two or more spectral bands for retrieving various features. A spectral index is calculated through the ratio of spectral bands where DNs in one spectral band are divided by DNs in another spectral band. Therefore, the ratio is calculated pixel by pixel through a nonlinear transformation (Schowengerdt 2007) represented as:

$$\text{Spectral index} = \frac{\text{DNs of band } m}{\text{DNs of band } n}$$

The spectral index is widely used in remote sensing, but it is not that simple as the above expression. Sometimes other mathematical operators are used between two or more spectral bands to form the numerator and denominator of the ratio, which is also referred to as modulation ratio. The spectral ratio is also normalized to provide the range to the BVs of the final image, which is commonly from -1 to $+1$ to define the particular feature and other features. “The image obtained through spectral index poses a less dynamic range than the original image, resulting in a reduction of radiance extremes due to topography. Therefore, the reflectance contrast between various features is enhanced through different spectral ratios” (Schowengerdt 2007).

Numerous spectral ratios are present in the literature for several features like vegetation indices, built-up indices, water indices, soil indices, and many more (Lillesand et al. 2008; Jensen 2016; Baranwal and Ahmad 2021). Below are a few examples of band ratios widely used for multispectral images.

$$\text{Ratio vegetation index : RVI} = \frac{\text{NIR band}}{\text{RED band}}$$

$$\begin{aligned} \text{Normalized difference vegetation index : NDVI} \\ = \frac{\text{NIR band} - \text{RED band}}{\text{NIR band} + \text{RED band}} \end{aligned}$$

$$\begin{aligned} \text{Normalized difference built-up index : NDBI} \\ = \frac{\text{SWIR1 band} - \text{NIR band}}{\text{SWIR1 band} + \text{NIR band}} \end{aligned}$$

$$\begin{aligned} \text{Normalized built-up area index : NBAI} \\ = \frac{\left[\text{SWIR2 band} - \frac{\text{SWIR1 band}}{\text{GREEN band}} \right]}{\left[\text{SWIR2 band} + \frac{\text{SWIR1 band}}{\text{GREEN band}} \right]} \end{aligned}$$

$$\text{Modified normalized difference water index : NDWI}$$

$$= \frac{\text{GREEN band} - \text{MIR band}}{\text{GREEN band} + \text{MIR band}}$$

NIR stands for near-infrared, SWIR stands for short-wave near-infrared, and MIR for mid-near-infrared; SWIR and MIR both represent the same spectral band.

Example 5: Error Matrix and Measures Through It

Geospatial data are analyzed through several visual, mathematical, and statistical methods, but before making any decision, analyzed geospatial data is checked for its accuracy, which is commonly done through error matrix or confusion matrix. This error matrix is created based on the agreement and disagreement of each sample data of the geospatial dataset validated through high spatial ground reference data (Jensen 2016). Thus, the error matrix itself is a dimensionless

measure used to determine producer's and user's accuracy in deriving the error of omission and commission, respectively. Overall accuracy and Kappa coefficient are also calculated through this error matrix to measure samples' agreement. Producer's, user's, and overall accuracy are the proportion of the samples that fulfill the agreement of sample in the column, in the row, and for the entire error matrix, respectively. Kappa analysis is another dimensionless measure evaluated through an error matrix to compare and get the difference between the analyzed and the reference map or image (Lillesand et al. 2008; Jensen 2016). Six types of Kappa coefficients are used in literature to determine agreement and disagreement of quantity and allocation of samples through two different approaches of an error matrix, i.e., the traditional approach of Kappa analysis (Chang 2008; Lillesand et al. 2008; Jensen 2016) and new approach developed a few years back (Pontius and Millones 2011).

Summary and Conclusion

Data analysis in geoscience is dependent on dimensionless metrics. Users use these measures in geospatial data analysis and decision-making even without knowing that they are dealing with dimensionless quantities. The examples mentioned here are elementary, frequently used, and essential in geoscience.

Definition

The *discrete prolate spheroidal sequences (DPSSs)* are maximally concentrated in both the time and frequency domains. This is a crucial property for applications in power spectrum estimation. The DPSSs comprise sets of real-valued orthonormal sequences (discrete functions) with the following properties: (i) They are limited within the spectral band $[-W, W]$, where $W > 0$. (ii) The total energy of the sequence (i.e., the sum of the squares of the amplitudes) over a finite time interval is maximized. The *time-limited DPSSs*, also known as the *Slepian sequences*, are orthonormal sequences with the following properties: (i) They are *time-limited* within a finite time interval. (ii) They exhibit maximal spectral concentration in the frequency band $[-W, W]$. The DPSSs are parametrized in terms of the length N of the temporal sequence, the bandwidth W , and the order $k = 0, 1, \dots, N - 1$ of the Slepian sequence.

Overview

In Fourier analysis, it is known that functions cannot be fully localized in both time and frequency. As an extreme example, consider the *cosine* function $\cos(2\pi f_0 t)$ with frequency f_0 . Its Fourier transform involves the sum of two Dirac delta functions, $\delta(f \pm f_0)$. The *cosine* is fully extended in time, but the delta functions are completely localized at $\pm f_0$. In less extreme cases, functions that are concentrated (localized) in either the time or frequency space are extended (delocalized) in the other. This trade-off between localization in the direct (space or time) versus the spectral domain is also evident in Heisenberg's uncertainty principle of quantum physics.

Since functions cannot be completely confined both in the temporal and spectral domains, a fundamental problem is how to optimally concentrate the energy of a signal in the time (frequency) domain if the signal is spectrally (temporally) confined. The optimal concentration problem was addressed in a series of papers by the mathematicians Slepian, Pollack, and Landau (Landau and Pollak 1961, 1962; Slepian and Pollak 1961; Slepian 1978, 1983). These theoretical advances established the framework for the development of powerful spectral estimation methods (Thomson 1982; Percival and Walden 1993). The DPSSs solve the maximal concentration problem in the case of discrete functions (i.e., for time series). The solution of the concentration problem for continuous functions is provided by the so-called *prolate spheroidal wave functions* (Slepian 1978). The DPSS development is reviewed by Slepian (1983).

Methodology

Consider a finite-length discrete time sequence $t_n = n\delta t$, $n = 0, 1, \dots, N-1$, where $N > 1$ and the time step is $\delta t > 0$. In addition, let $x(t)$ represent a square-summable (finite-energy) signal, sampled at the times t_n , i.e., $x_n = x(t_n)$, $n = 0, \dots, N-1$. The *discrete-time Fourier transform* (DFT) of the sequence is given by

$$\tilde{x}(f) = \sum_{n=0}^{N-1} \exp(-2\pi i f t_n) x_n. \quad (1)$$

The DFT is defined over the frequency interval $-f_N < f \leq f_N$, where $f_N = f_s/2$ is the *Nyquist frequency* and $f_s = 1/\delta t$ is the sampling frequency.

Formulation of the Concentration Problem

The concentration problem consists of finding all the finite-energy time sequences $\{x_n\}_{n=0}^{N-1}$ which maximize the *spectral concentration ratio*

$$\lambda = \frac{\int_{-W}^W |\tilde{x}(f)|^2 df}{\int_{-f_N}^{f_N} |\tilde{x}(f)|^2 df}, \quad \text{where } 0 < W < f_N. \quad (2)$$

The parameter λ , $0 \leq \lambda \leq 1$, measures the ratio of the energy contained within the spectral band $[-W, W]$ over the total energy. The DPSSs comprise N discrete functions, denoted by $v_n^{(k)}(W, N)$, $k = 0, 1, \dots, N-1$, that maximize λ and are also orthogonal to each other. The DPSSs are the real-valued solutions of the following set of equations (Slepian 1978)

$$\sum_{m=0}^{N-1} \frac{\sin 2\pi W(n-m)}{\pi(n-m)} v_n^{(k)}(W, N) = \lambda_k(N, W) v_n^{(k)}(W, N), \quad n = 0, 1, \dots, N-1. \quad (3)$$

The above system is equivalent to the following eigenvalue problem:

$$\mathbf{A} \mathbf{v}^{(k)} = \lambda_k \mathbf{v}^{(k)}. \quad (4)$$

In Eq. (4), $\mathbf{A}$ is the *prolate matrix* with elements

$$A_{n,m} = \frac{\sin 2\pi W(n-m)}{\pi(n-m)}, \quad n, m = 0, \dots, N-1,$$

$\{\lambda_k\}_{k=0}^{N-1}$ is the set of N eigenvalues, and the DPSS vectors $\mathbf{v}^{(k)} = (v_0^{(k)}, \dots, v_{N-1}^{(k)})^\top$ are the respective eigenvectors (" $\top$ " denotes the transpose), which form the *Slepian basis*. The eigenvalues λ_k represent the spectral concentration ratios for the respective eigenvectors $\mathbf{v}^{(k)}$.

For continuous functions of time, the concentration problem is solved by an integral equation whose eigenfunctions are the *discrete prolate spheroidal wavefunctions* (Slepian and Pollak 1961; Slepian 1978).

Properties of the Slepian Eigenvectors and Eigenvalues

The DPSSs possess certain useful mathematical properties (Slepian 1983; Percival and Walden 1993; Lii and Rosenblatt 2008):

1. The eigenvalues are distinct, real-valued, and positive: $1 > \lambda_0 > \lambda_1 > \dots > \lambda_{N-1} > 0$. The positive eigenvalues reflect the positive-definiteness of the prolate matrix $\mathbf{A}$.
2. The eigenvectors $\mathbf{v}^{(k)}$ are even or odd according to whether k is even or odd.
3. The eigenvector $\mathbf{v}^{(k)}$ has exactly k zeros in the open interval $(0, N-1)$.

Discrete Prolate Spheroidal Sequence, Fig. 1 The first five DPSS eigenvectors for $N = 256$, $W = 5/N$ (left plot) and $N = 512$, $W = 2.5/N$ (right plot). Horizontal axes: time sequence ($\delta t = 1$). Vertical axes: DPSS sequences $v_n^{(k)}(W, N)$

4. The eigenvectors that correspond to different eigenvalues are mutually orthogonal, i.e., each eigenvector $v^{(k)}$ is orthogonal to all eigenvectors $v^{(l)}$, $l = 0, \dots, k-1$.
5. The eigenvalues λ_k exhibit *clustering behavior*: Slightly fewer than $N(W/f_N)$ eigenvalues are very close to one, slightly fewer than $N(1 - W/f_N)$ eigenvalues are very close to zero, while the remaining (very few) eigenvalues are not close to either one or zero (Lii and Rosenblatt 2008). Hence, the number $N(W/f_N)$ (which equals $2NW$, if $\delta t = 1$) is a rough estimate (upper bound) of the number of significant eigenvalues.
6. The integer part of $2NW$ is an approximate estimate for the dimension of the space of functions that are “essentially concentrated” in both time and frequency.

The first five eigenvectors for two Slepian bases displayed in Fig. 1 illustrate the above properties. The plot on the left-hand side of Fig. 1 corresponds to $N = 256$, $NW = 5$, and $\delta t = 1$. The five respective eigenvalues λ_k are all very close to one. The plot on the right-hand side corresponds to $N = 512$, $NW = 2.5$, and $\delta t = 1$. The respective eigenvalues λ_k are given by 1, 0.99984, 0.99622, 0.95213, and 0.71389. Note that λ_0 appears as 1 because $1 - \lambda_0 \approx 3 \cdot 10^{-6}$.

Applications in Spectral Estimation

An important practical problem is the estimation of the *power spectrum* (*power spectral density*) of a process based on a finite set of observations (sample) of the process.

The following focuses on *wide-sense stationary, ergodic random processes* $Z(t)$, which are assumed to extend over the infinite time domain, i.e., $t \in (-\infty, \infty)$. The spectral density $S(f)$ of $Z(t)$ is well-defined and coincides with the Fourier transform of the autocorrelation function according to the Bochner-Khinchin-Wiener theorem. The time series $\{z_n\}_{n=0}^{N-1}$, where $z_n = z(t_n)$, represents a finite sample of $Z(t)$ (“ z ” is used herein to avoid confusion with maximally concentrated functions denoted by “ x ”).

Periodogram Estimator

The two-sided *periodogram estimate* $\hat{S}(f)$ of the spectral density based on $\{z_n\}_{n=0}^{N-1}$ is given by

$$\hat{S}(f) = \frac{\delta t}{N} \left| \sum_{n=0}^{N-1} z_n \exp(-2\pi i f t_n) \right|^2, \quad -f_N < f \leq f_N. \quad (5)$$

To obtain the one-sided estimate (for $0 \leq f \leq f_N$), $\hat{S}(f)$ in Eq. (5) is multiplied by two for all frequencies except for $f = 0$ and $f = f_N$.

An estimator is called *consistent* if its variance tends to zero as $N \rightarrow \infty$. Unfortunately, the periodogram $\hat{S}(f)$ is not consistent, because its standard deviation is as large as the expectation (mean), even as the sample size $N \rightarrow \infty$.

The periodogram also suffers from *spectral leakage*. This occurs because the finite observation window implies that $Z(t)$ is multiplied by a boxcar kernel (rectangular time window) which localizes the signal within the finite sampling interval.

Multiplication with the window function implies the convolution of the Fourier transform $\tilde{z}(f)$ with that of the boxcar kernel in the spectral domain; the convolution perturbs $\tilde{z}(f)$ by mixing values at neighboring frequencies.

Welch's Method

The method proposed by Welch reduces the variance of $\hat{S}(f)$ by dividing the sample into different segments which are allowed to overlap. A modified periodogram (see below) is estimated for each time segment, and the segment estimates are averaged to generate the Welch estimate of the power spectral density. The assumed stationarity of $Z(t)$ ensures that the modified periodograms represent approximately uncorrelated estimates of $S(f)$. Thus, averaging over different segments reduces the variance of the Welch estimate.

The *modified periodograms* involve the multiplication of the time series (signal) in each time segment with a *window function*. The latter vanishes outside the specific segment, peaks in the middle of this segment, and is symmetric around the peak. Windows thus suppress the values of the time series near the segments' edges. Overlapping segments prevent loss of information, since signal values near the edges of one window are also near the center of neighboring windows. In addition, windowing reduces potential inter-segment correlations that could arise due to segment overlap. Various windows with subtle differences that impact *spectral leakage* are used in the literature, including the Slepian zero-order DPSS. The Kaiser (also known as Kaiser–Bessel) window provides a simple approximation of the Slepian window based on Bessel functions.

Multitaper Method for Spectral Density Estimation

The *multitaper method* (MTM) was also developed to address spectral leakage in power spectrum estimation (Thomson 1982; Percival and Walden 1993). In MTM, the DPSSs are used to construct low-bias, statistically consistent spectral estimators that reduce spectral leakage.

The MTM is a *nonparametric* estimation method, because it is data driven and does not need a parametric model of the process. For example, the classical periodogram and Welch's methods are also nonparametric, while the *maximum entropy method* is parametric (Percival and Walden 1993).

The variance reduction of the spectral estimates is achieved in MTM by using a small set of mutually orthogonal windows (tapers), while Welch's modified periodogram uses a single data taper. The optimal MTM tapers consist of DPSS eigenvectors, which minimize spectral leakage by maximizing energy concentration in the main spectral lobe. Both the mutual orthogonality and the optimal time-frequency concentration are critical for the success of the multitaper technique.

The MTM estimate is obtained by averaging K modified periodogram estimates based on a respective set of K Slepian

tapers. Averaging reduces the variance of the power spectrum. Only the fraction of tapers $\sim 2N \frac{W}{f_N}$ that generate small spectral leakage are used. Asymptotic properties for the bias and variance of MTM spectral density estimates are studied in Lii and Rosenblatt (2008).

Let $S_k(f)$ denote the *modified periodogram* obtained with the k -th Slepian sequence, $v^{(k)}$:

$$S_k(f) = \delta t \left| \sum_{n=0}^{N-1} v_n^{(k)} z_n \exp(-2\pi i f t_n) \right|^2. \quad (6)$$

In the simplest MTM version, the power spectral density is estimated by averaging the K modified periodograms:

$$S_{\text{MTM}}(f) = \frac{1}{K} \sum_{k=0}^{K-1} S_k(f). \quad (7)$$

Other MTM versions use taper-dependent weights w_k (Percival and Walden 1993):

$$S_{\text{MTM}}(f) = \frac{\sum_{k=0}^{K-1} w_k S_k(f)}{\sum_{k=0}^{K-1} w_k}. \quad (8)$$

Both the MTM and Welch's method average over approximately uncorrelated estimates of the power spectral density. However, the two approaches differ with respect to how they decorrelate the modified periodograms. Welch's method uses different segments of the signal for each periodogram. MTM uses the entire signal, but the decorrelation is enforced by the orthogonality of the Slepian tapers.

Selection of the MTM Parameters

The MTM involves two competing parameters: the number of tapers K and the half-bandwidth W . In order to understand their role, recall that DFT has a frequency resolution equal to the *Rayleigh frequency* $f_R = f_s/N$; this is the minimum frequency difference that can be resolved by the DFT of a finite-duration signal.

For MTM estimation, a large value of K is desirable to reduce the estimate for the variance of the power spectrum. However, in practice, only the first $K = N(W/f_N) - 1$ of the DPSS eigenvectors provide negligible spectral leakage (Slepian 1978; Thomson 1982; Ghil et al. 2002). Hence, if p is the largest integer that does not exceed $N(W/2f_N)$, K is bounded by $K \leq 2p - 1$. On the other hand, the frequency resolution of the MTM is $f'_R \approx pf_R = W$. This implies a trade-off between spectral resolution and variance reduction. Optimal values for p and K thus depend on the length N of the time series and the desired spectral resolution.

DPSS in the Geosciences

The Discrete Prolate Spheroidal Sequences find numerous applications in the spectral estimation of climatic time series, geochemical, paleoclimatic, oceanographic, stratigraphic, and seismological data [Percival and Walden (1993), Ghil et al. (2002) and references therein]. Extension to spherical Slepian functions for spatial and spectral concentration problems on the sphere has applications in geodesy, geophysics, and oceanography (Simons and Wang 2011).

Software Implementations

In **MATLAB** and R software, the DPSS is implemented by means of functions called **DPSS**; multitaper power spectral density estimation is implemented by means of the **PMTM** function in **MATLAB** and the package **MULTITAPER** in R. In Python, this functionality can be found in the **SPECTRUM** module.

Summary or Conclusions

Discrete prolate spherical (Slepian) sequences provide a mathematically elegant solution to the problem of time-frequency concentration: They are limited within a specific time (spectral) window and also maximize the energy content within a finite spectral (time) window. Slepian sequences are used as window functions in Welch's modified periodogram spectral estimation. The DPSSs are also an integral component of the multitaper method of spectral estimation. The MTM leads to considerable improvements over the classical periodogram in terms of variance and spectral leakage reduction.

Discriminant Analysis

D. Arun Kumar

Department of Electronics and Communication Engineering and Center for Research and Innovation, KSRM College of Engineering, Kadapa, Andhra Pradesh, India

Definition

Discriminant Analysis, also called Linear Discriminant Analysis (LDA), is a mathematical approach to project the data points (in digital images data points are named as pixel values) from higher dimensional space to a lower dimensional space by removing the redundant features of data points. Removal of redundant features in the data points is identified as dimensionality reduction. The informative data in lower dimensions is obtained based on maximizing between-class variance and minimizing within-class variance. LDA is implemented in three important steps: (i) calculation of between-class variance; (ii) calculation of within-class variance; and (iii) constructing lower dimensional space with the data points having maximum between-class variance and minimum within-class variance.

Introduction

The utilization of Earth resources for various human needs has increased over the years. Assessment and monitoring of Earth resources are useful to plan for sustainable

development. Remote sensing is used to get the information about the resources through digital images with the advantages like spatial, spectral, temporal, and radiometric resolutions (Jensen 2004). Digital images consist of finite elements called pixels. The pixel values are also called digital numbers (DNs) (Gonzalez and Woods 2008). The pixel values in multispectral images are called pixel vector or a pattern. A pattern is associated and characterized by features. A pattern is a point in N dimensional feature space (Richards and Jia 2006).

Advancement in remote sensing technology has produced data with a higher number of features (also called higher dimensional data) (Richards and Jia 2006). Extracting the information from the higher dimensional data is a challenge in remote sensing data processing (Campbell 1987). One such type of data processing approach is data dimensionality reduction by preserving the information content (Lillesand et al. 2014). The dimensionality reduction techniques are broadly classified as (i) Unsupervised and (ii) Supervised (Fisher 1936). In Unsupervised dimensionality reduction approach, the techniques are applied to unlabeled data to extract the meaningful information. The methods like non negative matrix factorization (NMF), independent component analysis, (ICA) and principal component analysis (PCA) are mostly used unsupervised dimensionality reduction techniques (Jensen 2004). In supervised approach, the reduction techniques are applied on the labeled dataset. There are various methods of dimensionality reduction in labeled dataset such as neural networks (NNs), mixture discriminant analysis (MDA), and fuzzy rough set based functional dependency (FRFD) (Duda et al. 2000). Linear discriminant analysis (LDA) is mostly used dimensionality reduction technique for labeled dataset.

Linear Discriminant Analysis

LDA is also identified as a data classification technique that converts features of pixels into a lower dimensional feature space from a higher dimensional feature space (Bishop et al. 1995). The approach in LDA is based on increasing the ratio of between-class variance to within-class variance of a labeled dataset (Tharwat et al. 2017). In LDA, dimensionality methods are classified into two categories: (i) Class-Independent LDA (CILDA) and (ii) Class-Dependent LDA (CDLDA) (Fisher 1936). In CILDA, the pixels of all the classes are projected into a common lower dimensional feature space. Due to this reason, the CILDA method is called Class-independent approach. In CDLDA, the pixels of each class are projected to class-specific lower dimensional feature space (Fisher 1936). In CILDA and CDLDA, the pixels are projected into lower dimensional feature space and later, the

pixels are classified using various linear or nonlinear classification approaches (Shahdoosti and Mirzapour 2017).

There exist various LDA approaches, such as removal of null space within-class matrix as a solution of finding lower dimensional space in the case, if the number of features are higher than the number of samples in the dataset. If the number of features is greater than the number of samples in the dataset, it leads to small sample problem (SS) (Tharwat et al. 2017). The other approach of LDA is to use kernel functions to transform within-class matrix to a full-rank matrix. There are different variants of LDA technique to solve the SS problem such as direct LDA, PCA + LDA, regularized LDA, Null LDA, and kernel DLDA (Fisher 1936). The application of LDA is high in diversified fields like land use/land cover classification, face recognition, and cancer classification (Bishop et al. 1995).

The functional block diagram of LDA for dimensionality reduction is given in Fig. 1. In Fig. 1, the dimensionality of input data is reduced using CILDA/CDLDA approaches. In the next stage, the data points are projected into lower dimensional feature space. Later, the pixels in the lower dimensional space are classified using classifiers such as K-Nearest Neighbor (KNN), Minimum Distance to Mean classifier (MDM). The classifier generates the classified output map which is evaluated using ground truth data.

In the present study, the detailed description of various stages of LDA is provided. In the first stage, the between-class variance of data points from different classes is calculated to know the distribution of points in the feature space. In the second stage, within-class variance among the data points of same class is calculated to know the distribution of data points within the class. In the third stage, the details related to the construction of lower dimensional space with the data points having maximum between-class variance and minimum within-class variance is presented. An example of LDA on the labeled dataset is given in section “[Example](#).” The evaluation metrics of LDA is given in section “[Evaluation Metrics](#)”. The conclusions related to LDA are provided in section “[Conclusions](#).”

Discriminant Analysis, Fig. 1 Schematic flow diagram of linear discriminant analysis. The flow diagram consists of steps like input data, processing input data using CDLDA/CILDA, obtaining data points in lower dimensional space, classifying the data, and obtaining output classified map

Stage I: Calculation of Between-Class Variance

In a dataset of c classes, the between-class variance of i th class is the distance between the mean of i th class (μ_i) and the mean of the dataset (μ). The overall between-class variance (V_D) of dataset is given as:

$$V_D = \sum_{k=1}^c n_k V_k, \quad (1)$$

where n_k is the number of samples or data points or pixels in i th class, c is the number of classes in the dataset. V_i is the variance of i th class. The variance of i th class (V_i) is calculated as:

$$(\mu_i - \mu)^2 = W^T V_i W, \quad (2)$$

where W is the transformation matrix of LDA. The LDA approach maximize the between-class variance, that is, maximize the distance between classes and project the points into lower dimensional space (Tharwat et al. 2017).

Stage II: Calculation of Within-Class Variance

The within-class variance of i th class is defined as the difference between the mean and the pixel values of respective class. The LDA technique projects the pixels into lower dimensional space such that the pixels have minimum within-class variance. The within-class variance of each class in the dataset (V_{Wj}) is calculated as:

$$V_{Wj} = \sum_{k=1}^{n_j} (P_{kj} - \mu_j)(P_{kj} - \mu_j)^T, \quad (3)$$

where P_{kj} represents the k th pixel of j th class, μ_j is the mean of j th class. The detailed explanation of LDA with an example is given in (Tharwat et al. 2017).

Stage III: Construct Lower Dimensional Space

The lower dimensional space for projecting the pixels is computed using transformation matrix (W) in LDA. The transformation matrix (W) is calculated based on Fisher's criterion as:

$$V_{Wj} W = \lambda V_D W, \quad (4)$$

where λ is the eigenvalues of matrix W . The solution of Eq. 4 is obtained by calculating the eigenvalues ($\lambda = \lambda_1, \lambda_2,$

$\lambda_3, \lambda_4, \dots, \lambda_p$) and eigenvectors ($v = v_1, v_2, v_3, v_4, \dots, v_p$). Eigenvalues are scalar and the eigenvectors are derived from the eigenvalues which are nonzero vectors. The eigenvalues and eigenvectors satisfy the Eq. 4 and provide the information related to reduced feature space after the application of LDA.

In the multidimensional space, the eigenvectors represent the directions of the new space, and the corresponding eigenvalues represent the magnitude of the eigenvectors. Each eigenvector represents a feature axis of LDA space and the eigenvalues represent the intensity of eigenvector. The intensity of eigen vector represents its ability to discriminate different classes in the feature space by increasing between-class variance, and by decreasing within-class variance of each class. The eigenvectors with highest eigenvalues are considered to construct lower dimensional feature space and the eigenvectors with lowest eigenvalues are neglected. The selected eigenvectors are also called principal components and each principal component (a vector) is a feature axis in lower dimensional space. The data points or pixels are then projected into lower dimensional space using the transformation matrix. The pixels that are projected into lower

Agriculture	200

Discriminant Analysis, Fig. 2 Distribution of highly overlapping data points in Band 1 and Band 2 feature space. Data points with label A are Urban Dense, B – Urban Sparse, C – Forest, D – Water, E – Agriculture

dimensional space are classified using the classifiers such as KNN, MDM, Neural networks, etc.

Example

In the present study, five major land use/cover classes for IRS LISS III dataset of Mumbai region, India, were considered. The classes in the dataset are Urban Dense, Urban Sparse, Water, Forest, and Agriculture. The dataset consists of 1000 samples/pixels such as 200 samples from each class. The

details of the dataset are given in Table 1. Each pixel is characterized by four features (four spectral bands such as Band 1, Band 2, Band 3, and Band 4) and 1000 pixels are projected as 1000 points in 4D feature space. The distribution of 1000 pixels in Band 1 and Band 2 feature space is given in Fig. 2. In Fig. 2, the pixels of five classes are highly overlapped with less chances of separability. The dense distribution of pixels in the feature space (Fig. 2) is transformed to lower dimensional feature space with good separability between the pixels of different classes.

LDA is applied on the input dataset and the corresponding principal components are computed (as mentioned in the above sections) to project the points in to lower dimensional feature space. The two principal components PC1 and PC2 with the corresponding variance ratio are given in Fig. 3. In Fig. 3, PC1 has maximum variance ratio (98%) which indicate that the transformed points have high separability along the PC1 axis. The separability of data points in the lower dimensional space along the PC1 axis with respect to PC2 axis is given in Fig. 4. Later, the data points with high separability in the lower dimensional feature space are classified using various type of linear/non-linear classifiers or parametric/non-parametric classifiers. The classifiers such as KNN, MDM, NN, decision trees, and random forest are frequently used for data classification (Richards and Jia 2006). In the present study, the overall accuracy of KNN classifier ($K = 5$) before the application of LDA on the dataset is 95% while the overall accuracy of KNN classifier ($K = 5$)

Discriminant Analysis, Fig. 3 The two principal components namely PC1 and PC2 with corresponding variance ratio

Discriminant Analysis, Fig. 4 Data points in 2-D feature space with maximum separability along PC1 axis. Data points with label A are Urban Dense, B – Urban Sparse, C – Forest, D – Water, E – Agriculture

after LDA on the dataset is 98%. Application of LDA on LISS III dataset improved the class separability which resulted in 3% improvement in the overall accuracy for KNN classifier.

Evaluation Metrics

The accuracy of classified pixels/data points is measured using different metrics like users' accuracy, producers' accuracy, overall accuracy, kappa coefficient, and dispersion score. These metrics are quantified from the confusion matrix or accuracy matrix (Jensen 2004).

Conclusions

Advancement of remote sensing sensor technology produced a large amount of spatial data. There are various data processing techniques such as classification, clustering, and regression analysis. Data/pixel classification is mostly used preprocessing technique in remote sensing data analysis. Pixel classification in the highly overlapping classes is a challenging task. LDA is used to improve the separability among the classes by reducing the number of features. In the present study, the application of LDA on LISS III dataset reduced the number of feature from four to two. Also, the data points in lower dimensional feature space have high separability. Application of LDA followed by KNN classifier improved the overall accuracy by 3% (with 98% overall accuracy value LDA + KNN) for IRS LISS III dataset.

Discriminant Function Analysis

Norman MacLeod

Department of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, China

Definition

Discriminant Function Analysis – A family of data analysis methods that attempt to find a linear combination of variables that optimally separates two or more groups, categories, or classes of objects, samples, or events.

Introduction

It is often the case that earth scientists become involved with the multivariate analysis of datasets that exhibit subgroup-level structure that has been established a priori, at the outset of an investigation. If this knowledge is irrelevant to the question(s) being investigated, or if the purpose of the investigation is exploratory in the sense of determining whether differences within the pooled sample reflect the structure of these a priori subgroupings, it can be appropriate to employ pooled-sample, ordination-based, data-analysis methods (e.g., principal components analysis, principal coordinates analysis, factor analysis). For example, if a dataset is composed of three or more variables drawn from two groups of specimens, and the variable(s) exhibiting largest difference between group means is/are also the variable(s) with the largest variance(s), it will often be the case that an eigenanalysis of these data will reveal the subgroup-level structure on the first few eigenvectors (Fig. 1a). However, if a dataset is composed of three or more variables drawn from two groups of specimens, and the variable(s) exhibiting largest between-groups difference(s) is/are not the variable(s) with the largest variance(s) (Fig. 1b), the existence of group-level structure may only be apparent on higher-level eigenvectors whose

Discriminant Function Analysis, Fig. 1 Simulated data demonstrating the inability of eigenvector-based ordination methods (e.g., PCA, PCoord. Factor Analysis) to be relied on to identify subgroup-level structure in multivariate datasets. (a) Results from the analysis of a three-variable dataset in which a discontinuity in variation was placed in the variable exhibiting the greatest variance. (b) Results from the analysis of a three-variable dataset in which a discontinuity in variation was placed in the variable exhibiting the least variance. Note that, despite

PCs 1 and 2 including information from all three variables, there is no hint of the existence of subgroup structure in B. This discontinuity would be revealed in ordination plots that included PC-3 for this dataset. But in higher dimensional data it would very easy to overlook this structure if it was located in low-variance variables. This discrepancy demonstrates why discriminant analysis is required if subgroup structure is suspected and is a target in many data-analysis situations

interpretive significance may be overlooked, or perhaps on none at all. In these instances it would be grievous error to conclude that subgroup-level structure either did, or did not, exist in these data on the basis of an analysis that was based only on consideration of the pooled-sample structure. Unfortunately, the published earth-science literature is replete with examples of researchers who have used pooled-sample data-analysis methods to test hypotheses concerning the existence of subgroup-level structure or, even more seriously, the lack thereof. It was to address the complications that arise in the consideration of datasets in which there is reason to believe subgroup-level structure exists that methods of linear discriminant function analysis were developed.

Discrimination, Classification, and Identification

Before embarking on a discussion of linear discriminant analysis, it is necessary to distinguish between the processes of discrimination, classification, and identification as these terms are often confused and, indeed, have different meanings in the fields of earth science, mathematics, and computer science. Discrimination represents any attempt, by means of quantitative procedures, to discover and define a combination of variables that can be used to maximize the differences between two or more a priori-defined groups or subgroups belonging to a single group. The mathematical functions or models best suited to the discrimination task may be linear or nonlinear, continuous or discontinuous, etc. Irrespective of

these differences, the discrimination problem is a problem of optimization.

Discrimination requires knowing how many groups need to be separated from one another at the outset of the investigation. In order for the discriminant functions so defined to have any practical utility outside the context of the data used to determine them, it is also required that the samples used to estimate these functions be representative statistically of the populations from which they were drawn as it is these populations that are the actual targets of the investigation. This requires careful attention be paid to the collection of the samples used in a discriminant analysis. If these samples are biased or nonrepresentative of the larger populations from which they were drawn all results obtained from their analysis will only apply to the samples themselves, not to the larger populations. Finally, if the actual targets of the hypothesis tests under consideration are these larger populations, performance of the estimated discriminant functions must be tested via reference to independent, external samples that were not used to determine the discriminant functions in question.

Classification is the act of determining how many subgroups a larger group may be subdivided into and/or the act of determining which larger group to which a subgroup may be assigned (e.g., fossil species attributed to a genus, minerals attributed to a mineral family). As such, it is a completely different and distinct procedure from that of discrimination. If classification is the goal the procedure is not one of optimization, but rather one of discovery. In quantitative data analysis this discovery is often made when methods of ordination

or similarity/dissimilarity clustering detect subgroupings of objects whose variable values are either completely or relatively distinct from other subgroupings. Accordingly, a much wider array of numerical procedures can be brought to bear on the question of classification than is the case for discrimination. Moreover, in the vast majority of instances it will be impossible to know how many completely or relatively distinct subgroupings of objects are present in any given dataset. It must also be assumed that different types of quantitative rule sets might be involved in the recognition of different subgroupings that exist, especially when the dimensionality of the data is high. Complicating this task further is the fact that the number of specimens required by an analysis must increase near exponentially as dimensionality increases in order to maintain a density of observations in the variable space sufficient to be able to recognize subgroupings of objects stably (= the curse of dimensionality, see Altman and Krzywinski 2018).

Once a classification has been devised, qualitative, simple qualitative or complex numerical procedures can be employed to facilitate the placement of unknown objects into the classification scheme. This is identification. Classifications are utilitarian in the sense of the same objects being allocated to different categories within different classification systems that may be based on different types of variables, observations attributes, and/or measurements. Identification procedures need neither be quantitative nor optimized though there is obvious value in placing such decisions on an optimized, quantitative footing where possible. Identification can also become part of the discovery/classification process in the sense that objects (or collections of variable values) falling outside the ranges of groups or subgroupings already in the classification system may signal the presence or existence of new subgroup-level categories.

These distinctions between discrimination, classification, and identification must be kept in mind when undertaking either research or applications in any of these areas. In addition, when reading the works of researchers that employ these terms care must be taken to understand how the terms they use map onto the concepts described above, lest great and unnecessary confusion result (e.g., computer scientists typically use the term “classification” to refer to the concept of discrimination).

Fisher (Two-Group) Linear Discriminant Analysis

Linear discriminant analysis was developed originally by R. A. Fisher (1936) to address the problem of optimally allocating individual sets of observations to one of two subgroupings using a linear classification function that maximized the F ratio of $\mathbf{B}/\mathbf{T}$ where $\mathbf{B}$ represents the between subgroupings variance-

covariance matrix and $\mathbf{T}$ represents the total (= pooled sample) variance-covariance matrix.

Fisher's original method was restricted to the consideration of only two subgroupings and geometrically amounted to solving the problem by maximizing the separation of their multivariate means relative to their pooled sums of squares and cross products. This calculation resulted in a function of the general form:

$$y = \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 \cdots + \beta_p x_p \quad (1)$$

where the x values represent real-variable values of collected data and the β coefficients refer to weights assigned to the variables that represent the angular relation between the variable and the linear discriminant vector. Under Fisher's original model it is assumed that the optimal linear discriminant vector is oriented at some angle to all variable vectors such that no single variable accounts for the maximum separation of multivariate means. In matrix notation this two-subgroup linear discriminant vector can be found by solving the following equation for λ .

$$S\lambda = D \quad (2)$$

where

$$S = \frac{S_A + S_B}{n_a + n_b - 2} \quad (3)$$

$$S_A = \sum_{j=1}^m \sum_{i=1}^{n_a} x_{aj} x_{aj} - \frac{\sum_{i=1}^{n_a} x_{ai} \sum_{i=1}^{n_a} x_{ai}}{n_a} \quad (4)$$

$$S_B = \sum_{j=1}^m \sum_{i=1}^{n_b} x_{bj} x_{bj} - \frac{\sum_{i=1}^{n_b} x_{bi} \sum_{i=1}^{n_b} x_{bi}}{n_b} \quad (5)$$

$$D = \bar{A} - \bar{B} \quad (6)$$

Objects, samples, or events described by the set of variables may be projected onto the discriminant axis by pre-multiplying λ by the observed data values. By convention, the decision point that separates subgroup domains along the linear discriminant function is usually taken to be the midpoint between the subgroup centroids. For a simple analysis of linear discrimination between beach sands and offshore sands collected from the Texas Gulf Coast (see the Davis 2002 SANDS.txt datafile; <https://bcs.wiley.com/he-bcs/Books?action=index&bcsId=1479&itemId=0471172758>) application of these equations produces the results shown in Fig. 2.

Discriminant Function Analysis, Fig. 2 Results from a classic Fisher (1936) (two-group) linear discriminant analysis applied to a marine sand size, sorting dataset. (a) data values plotted in the space of the original variables with the Fisher linear discriminant function. (b) Histogram of

the beach sand and offshore sand data projected onto the linear discriminant function. Note the broad range of distribution overlap that characterize each of the original variables in **a** and the manner in which this overlap has been minimized in **b**

Multiple Group Linear Discriminant Analysis (Canonical Variates Analysis)

While the classic, formulation of linear discriminant analysis established by Fisher (1936) is perfectly serviceable for the simple two-group case, most practical discriminant analysis problems involve more than two groups or subgroups of a single group. Fortunately this procedure has been generalized and, providing sufficient sample sizes are available, can be used to analyze any number of subgroups. The modern formulation of this extension, termed canonical variates analysis (CVA), takes advantage of several important improvements suggested by Bartlett (1951) and Rao (1952).

The general form of Eq. 1 is used to define a set functions that will yield the maximum possible F value while not being correlated the other discriminant functions. In this way the discriminant functions calculated as a result of CVA can be regarded as being similar to principal components. However, an important difference between PCA and CVA that must to kept in mind is that, while the canonical variates are orthogonal to one another in their own space, they will not be orthogonal to one another in the space of the original variables. This unfortunate feature can make the qualitative interpretation of individual canonical variates difficult, but interpretation can often be aided for some types of data (e.g., morphological) via modeling of the canonical variates space. Another difference between CVA and PCA is that, for a discriminant problem involving k groups, only $k-1$ canonical variates will result irrespective of the number of variables included in the data.

Finding the equations of the canonical variates is a surprisingly simple procedure involving a logical partitioning of the

total (pooled-sample) variance-covariance matrix T , into two components, a within-groups variance-covariance matrix W and a between-groups variance-covariance matrix B , as follows.

$$T = B + W \quad (7)$$

where

$i = i^{\text{th}}$ object or sample

$j = j^{\text{th}}$ variable

$k = k^{\text{th}}$ group

$$\bar{X}_{kj} = \frac{\sum_{i=1}^{n_k} x_{kij}}{n_k} \quad (8)$$

$$\bar{\bar{X}}_j = \frac{\sum_{k=1}^g \sum_{i=1}^{n_k} x_{kij}}{N} \quad (9)$$

$$T_{pq} = \sum_{k=1}^g \sum_{i=1}^{n_k} (x_{kij} - \bar{\bar{X}}_p) (x_{kij} - \bar{\bar{X}}_q) \quad (10)$$

$$W_{pq} = \sum_{k=1}^g \sum_{i=1}^{n_k} (x_{kij} - \bar{X}_{kp}) (x_{kij} - \bar{X}_{kq}) \quad (11)$$

$$B_{pq} = \sum_{k=1}^g n_k (\bar{X}_{kp} - \bar{\bar{X}}_p) (\bar{X}_{kq} - \bar{\bar{X}}_q) \quad (12)$$

Of course, once the T matrix has been calculated, calculation of either the W or the B matrix will be sufficient to determine the final matrix via subtraction. Next, the

Discriminant Function Analysis, Fig. 3 Results of an example CVA of the Anderson-Fisher *Iris* data. (a) Ordination of the first 35 specimens of each of the three *Iris* species in the space of the two canonical variates. Note extent of the between-groups separation and the fact that, in this dataset, virtually all of the between-groups separation is subsumed on CV-1. (b) Confusion matrix for the set of training specimens based on the proximity for projected specimen dataset with respect to group centroids in the CV space. While group discrimination appears to be excellent for

this specimen set, such a result does not necessarily indicate a comparable level of performance will be achieved for non-training datasets. (c and d). scatterplots of sepal length/width (c) and petal length/width (d) datasets along with the back-projected positions, lengths, and orientations of the canonical variate vectors. Note that, despite these vectors exhibiting an orthogonal orientation relative to each other in the canonical variates space (a), they are not orthogonal in the space of the original variables

eigenvectors of the $W^{-1}B$ matrix are calculated. These eigenvectors will contain the weight loading (β) values of the set of $k-1$ canonical variates (= discriminant function) while their eigenvalues will represent an indication of how much separation between group centroids is accounted for by each canonical variate. For illustrative purposes, the set of original data values may be projected into the space formed by the canonical variates by premultiplying them by the matrix of eigenvectors. Campbell and Atchley (1981) have pointed out that CVA is, in essence a two-stage eigenanalysis-based rotation of the original data, the first of which treats the dataset as a whole and the second of which focuses on the group centroids with an intermediate eigenvalue scaling step that serves to equalize across-group variances.

Fisher (1936) originally used a set petal and sepal lengths collected from three different *Iris* species by Edgar Anderson

and published in 1935 in the Bulletin of the American *Iris* Society to illustrate his concept of discriminant function analysis. Since then the “Fisher” *Iris* data has been used by countless statisticians to develop and illustrate the use of new methods of quantitative data analysis. Figure 3 illustrates results obtained from a classic CVA of these data.

Performance Testing and Statistical Significance

As with Fisher’s LDA, the classic (but not the only) method of allocating unknown objects or samples (= sets of variable values) is to determine which group centroid in the CV space an object’s or sample’s projected position in the full CV space is closest to. Such calculations are summarized typically in tabular form (see Fig. 3b), in what is termed a “confusion

Discriminant Function Analysis, Fig. 4 Results of use of a validation set of 15 specimens from each of the Anderson-Fisher *Iris* species to test use of the CVs shown in Fig. 3 as tools for accurate species identification. (a) scatterplot of the projected positions of the validation-set specimens into the training-set CV space. (b) Confusion matrix for the

validation-set specimens based on proximity of their projected positions in the CV space with respect to the training-set group centroids. In this case all validation set specimens projected to positions closest to the training-set centroids (+) of the species to which they had been assigned a priori

matrix.” From this table a wide variety of descriptive summaries may be calculated that, together, provide an indication of the degree to which the discriminant analysis was successful in separating the subgroups (see Tharwat 2018). While informative in and of itself, a confusion matrix calculated from the training set should be interpreted with a fair amount of skepticism. Such results are valid for the training-set data but may not provide an accurate indication of the degree to which the estimated discriminant functions will be successful in achieving accurate identifications of objects that were not included in the training set. For this reason it is always preferable to randomly subdivide a sample of observations or measurements into a training dataset and a (usually smaller) testing or validation data set, so the performance of the discriminant functions in a real-world situation can be assessed objectively. Of course, this test implicitly assumes the total sample to hand represents a statistically valid sample of the populations from which the samples were drawn, and so underscores the absolute importance of sample quality in any discriminant analysis situation. Sets of discriminant functions that return excellent results for the training set, but much poorer results for the testing or validation set, are said to be “overtrained.” Figure 4 illustrates results of an independent validation set test of the “Fisher” *Iris* discriminant functions shown in Fig. 3.

If, as is often the case, an insufficient number of objects or samples are available to create both a training dataset and a testing or validation dataset, performance testing of a sort can still be carried out using the calculation-intensive “jackknife” strategy (Manly 2004). Under this procedure, a full set of n CVAs are carried out on datasets from which a different object or sample has been sequestered successively. This

sequestered object or sample is then identified by the resulting discriminant functions and the process repeated until all members of the training set have been sequestered and then re-identified independently by discrimination functions estimated on the non-sequestered data. Nevertheless, care must always be taken in interpreting jackknifed results as their use makes the statistical validity of the training set data even more of an issue. In all cases valid testing or validation datasets drawn independently from the populations of interest should be collected if at all possible and the direct analysis of such data preferred over the jackknife-estimation alternative.

A wide range of statistical tests are available for both Fisher’s LDA and CVA analysis in order to determine whether the separation between subgroup means along the LDA axis and/or within the CVA space is sufficient, relative to subgroup variances, to warrant rejection of the null hypothesis of no difference. These tests include Hotelling’s T^2 , the log likelihood ratio (ϕ), Wilk’s lambda (λ), Roy’s largest root (λ), Pillai’s trace (V), and the Lawes-Hotelling trace (U) (see Manly and Alberto 2017). Each of these tests assumes multivariate normality and equality of covariance matrixes across all groups/subgroups included in the sample. Advocates of each test claim theirs is robust to violations of these assumptions, but no guidance is provided typically as to how serious such violations might need to be before the test results become unreliable. If questions arise regarding the validity of these assumptions, perhaps the best alternative is to avail oneself of either the Monte Carlo or bootstrapping re-sampling strategies in order to create a valid empirical distribution “on the fly” for use in formal hypothesis testing (see Manly 2004). However, once again, this strategy raises

the issue of how representative of the parent population(s) sets of samples might be. Manly and Alberto (2017) also describe a Mahalanobis distance (D^2) test that may be used to evaluate the question of whether any individual set of measurements really belongs to the group to which it has been assigned statistically, via reference to the χ^2 distribution.

Conclusion

Many earth-science data analysts seem to assume that subgroup-level structure will be aligned with the major direction of variance within the pooled sample. In many cases this will be true and, when it is true, aspects of such structural relations can be revealed by pooled-sample ordination methods (e.g., PCA, PCoord, factor analysis). But this structural arrangement will not be true invariably. In order to visualize and/or test hypotheses of group or subgroup difference, it is necessary to employ some form of discriminant analysis irrespective of what pooled-sample ordination plots may, or may not, show. Fisher (two-group) and multi-group linear discriminant analysis represent two powerful approaches to the analysis of subgroup structure in multivariate datasets. Care must be taken when applying these methods to very high dimensional datasets and datasets characterized by small and/or unbalanced sample sizes. Nevertheless, these linear approaches represent traditional and (still) attractive alternatives to more powerful machine-learning methods (which often require enormous sample sizes) in many earth-science contexts.

Biography

John H. Doveton is a geologist best known for his pioneering use of computers in subsurface investigations, and especially in the quantitative interpretation of well logs. John has been instrumental in expanding the scope of well log analysis, with its narrow focus on porosity and permeability, into the broad expanse of petrophysics dealing with all aspects of composition and texture of rocks in the subsurface.

John was born in Croydon, Surrey, England in 1944. He studied geology at Oxford University, receiving BA and MA degrees. His doctoral studies (PhD, 1969) were done at the University of Edinburgh, employing the university's computer for analyses of sedimentological data. This experience led to a yearlong postdoctoral fellowship at the Kansas Geological Survey, and in turn to a position in Calgary with Mobil Oil Canada.

As a new recruit to the oil business, Mobil provided John an intense schooling in all aspects of applied petroleum geology that an exploration geologist might need, including the interpretation and analysis of well logs. This proved fortuitous, because John recognized that this was an area where his mathematical skills and computing background could be especially useful. Over the next several years, in addition to his well site duties, John prepared a number of quantitative studies for Mobil, which eventually resulted in a return to

Kansas for a cooperative study. This quickly evolved into a permanent position in the Kansas Geological Survey, where John remained for the next 45 years.

John's first years at Kansas were devoted to probabilistic assessment in petroleum exploration and investigation of a wide variety of multivariate procedures for their potential utility in geologic studies. He also developed materials for a graduate course in well log analysis for engineers and geologists, a subject he continued to teach throughout his career.

Experience with statistics lead John to regard wireline well logs as mathematical matrices that could be manipulated by computer. On this basis, he designed an innovative computer program for well log analysis that became preeminent in both the petroleum industry and academia. Subsequently, John wrote algorithms for petrophysics that could be implemented on ordinary spreadsheet programs. These were used to provide students with practical experience in his graduate and professional courses on log analysis.

In addition to his regular courses on log analysis at the University of Kansas, John served as visiting professor at numerous other universities, both in the USA and abroad. He also offered his short courses on petrophysics to oil companies and professional groups all over the world. His extensive course notes were provided in versions customized for each audience. John has published extensively on topics in mathematical geology; his resume includes hundreds of articles, reviews, and three textbooks on log analysis and petrophysics.

²Discipline of Earth Sciences, Indian Institute of Technology, Gandhinagar, Palaj, Gandhinagar, India

Definition

Earth surface processes (ESP) shape earth's topography by adding or removing mass from earth's surface by erosion, transportation, and deposition. Records of earth surface process have been of interest as archives of past events like tectonic activity, climate change, and eustatic sea level change. Advent of new chronological tools led toward quantitative understanding of ESP, which further resulted in a new set of research questions about cause–effect relationship between landforms, processes, and controls. Hence, recently, mathematical concepts have been widely used to quantify and model these processes, which provide a comprehensible idea into the physics of these processes. The mathematical concepts also enable to model and infer the highly nonlinear cause–effect characteristics prevalent in ESP.

Earth Surface Processes (ESP) and Landforms

Earth's landscape is sculpted by both surface and subsurface components. These processes are influenced by the tectonic motion, base-level change, and climate change, which supply and deduct mass from the surface and create various patterns on the earth's surface. ESP are driven primarily by some form of fluid (i.e., air, glacier, and water) motion and operate at a decadal to millennial time scales. Recently, anthropogenic activities have significantly affected the ESP. The role of various controls on ESP through different thresholds leads

to a nonlinear and complex response of geomorphic systems to external controls.

Complexities in geomorphic systems are also caused by (1) the action of various drivers, i.e., wind, glacial, fluvial, hillslopes, or coastal, and (2) their operations and interactions at different spatiotemporal scales. Understanding ESP and its interactions at cross-over of scales is the key to unravel the complexities in landscape patterns and its evolutionary trajectory. Interestingly, mathematical concepts provide these tools to study and understand the across-scale linkages and inherent complexities present in ESP. For example, basic equations of sediment grain transport are being applied to study evolutionary trajectories of landscapes in different scenarios of climate change and tectonics. Hence, the application of mathematical concepts in ESP studies is providing new insight to earth surface science. This entry focuses on the advancement and application of mathematical concepts in ESP studies.

Mathematical Concepts to Study Various ESP and Landforms

Mathematical approaches for ESP range from modeling the dynamic processes resulting in the complex landscape in terms of partial differential equations (PDE) to the representation of the earth surface forms in terms of known mathematical functions. PDE models are derived from the conservation of mass and specific transport laws relating mass flux to physical characteristics of topography (such as gradient) (Tucker and Hancock 2010). In the following section, we compile a few of the major mathematical concepts, which are being implemented in modern-day ESP studies.

Differential Equation

The general governing equation for the spatiotemporal evolution of earth surface topography in a fluvial domain is a conservation equation:

$$\frac{\partial h}{\partial t} = -\nabla \cdot q_s + U \quad (1)$$

Here, h is elevation of topography, q_s is the sediment flux across a cross-section, and U is a source (or sink) term. Sediment flux is related to elevation through the following constitutive relation:

$$q_s = uh - D\nabla h \quad (2)$$

where u is the advection velocity (celerity), and D is the diffusivity. Correspondingly, the first term is the advective flux and second is the diffusive flux. Governing equation for elevation is obtained by combining Eqs. 1 and 2 as an advection-diffusion equation:

$$\frac{\partial h}{\partial t} = -\nabla \cdot (uh) + \nabla \cdot (D\nabla h) + U \quad (3)$$

To obtain a unique solution, we need a set of boundary conditions (BC) and an initial condition (IC). While the IC can take any arbitrary form, owing to the specifics of the system and the problem, generally we have for the BC: (1) Dirichlet (fixed boundary elevation) (2) Neumann (fixed flux), and (3) Robin condition (a combination of flux and elevation as fixed). The solution to this PDE (Eq. 3) gives us a transient form of elevation at any point of time and space. There are two special cases of the general governing equation, (1) hillslope evolution process, when diffusion is important and (2) bedrock channel evolution, when advection is important, as discussed below.

Hillslope Evolution

Evolution of a hillslope can be mathematically represented as a linear diffusion process, and the governing equation in 1-D is:

$$\frac{\partial h}{\partial t} = U(x, t) + D \frac{\partial^2 h}{\partial x^2} \quad (4)$$

The transient form of the diffusion equation can be solved using the method of separation of variables (Fourier series method) or integral transform methods. The transient solution can then be used for morphological dating of geomorphic landforms. For instance, a general solution for the evolution of the gradient of a fault scarp (in the absence of uplift) is given as (Pelletier 2008):

$$\frac{\partial h}{\partial x} = \frac{\alpha - b}{2} \left(\operatorname{erf} \left(\frac{x + a/(\alpha - b)}{\sqrt{4Dt}} \right) - \operatorname{erf} \left(\frac{x + a/(\alpha - b)}{\sqrt{4Dt}} \right) \right) + b \quad (5)$$

where α is the initial scarp slope, $2a$ the scarp offset, and b is the regional slope, and erf is error function. The product of the

age (t) and diffusivity (D), morphologic age (Dt), is related to the length scale of diffusion and dictates the development of the final form of the scarp. With a calibrated value of D , we can use the morphologic age to calculate the numerical age of a fault scarp and slip rate along the fault.

Further, in the case of a nonlinear transport, the governing equation will be modified to (Roering et al. 1999):

$$\frac{\partial h}{\partial t} = U - \frac{\partial}{\partial x} \left(\frac{-D(\partial h / \partial x)}{1 - [(\partial h / \partial x) / S_c]^2} \right) \quad (6)$$

Here, S_c is the critical hillslope gradient at which down-slope sediment fluxes become infinite. Nonlinearity can also arise from considering nonlocal effects of topographic gradient on flux, as opposed to the locally defined sediment flux as in the case for Eqs. 4 and 6. This nonlocal sediment flux can be expressed in the form of flux at a given point as a weighted average of the upslope topographic attributes:

$$q_s(x) = -K \int_0^x g(l) \nabla h(x-l) dl \quad (7)$$

where $g(l)$ is a kernel performing a weighted average of local gradients upslope of the point of interest x as they contribute to the sediment flux at the point x . It has been shown (Foufoula-Georgiou et al. 2010) that when the weighting function $g(l)$ has no characteristic length scale, i.e., $g(l) \sim l^{1-\infty}$, Eq. 7 takes the form of a fractional derivative:

$$q_s(x) = -K \nabla^{\infty-1} h(x) \quad (8)$$

The resulting governing equation for topography thus becomes

$$\frac{\partial h}{\partial t} = U + K \nabla^{\infty} h \quad (9)$$

The transient solution to Eqs. 6 and 9 can be achieved using numerical methods (Foufoula-Georgiou et al. 2010; Perron 2011).

Besides the fluvial domain, the diffusion equation has also been used to model glacial erosion (Herman et al. 2018) and aeolian transport (Pelletier 2018). This highlights the generality and adaptability of mathematical concepts to carryout physics-based modeling across multiple domains of ESP studies.

Bedrock Channel Evolution

Bedrock channel incision is a fundamental process for understanding the trajectories of landscape evolution. It is commonly represented by the area-based Stream Power Incision

Model (SPIM), explicitly representing the universally observed inverse power relation between channel slope and drainage area (Howard et al. 1994), and can be presented as follows:

$$\frac{\partial h}{\partial t} = U - K'A^{\beta'}S^{\zeta} \quad (10)$$

If we substitute area (A) with distance from channel head (x) using Hack's Law (section "Power-Law Function"), the governing equation transforms to

$$\frac{\partial h}{\partial t} = U - Kx^{\beta}S^{\zeta} \quad (11)$$

where $\beta = \beta'/H$ and $K = K'/K_H^{\beta'/H}$. K' and K are the erodibility coefficient, while β' (β) and ζ are area (distance) and slope exponents, respectively. H is the Hack's exponent and K_H is the Hack's coefficient. Equation 11 can be compared to a 1-D advection equation of the following form:

$$\frac{\partial h}{\partial t} = U(x, t) - u(x, t) \frac{\partial h}{\partial x} \quad (12)$$

which suggests that Eq. 11 is basically an advection equation with a celerity as $Kx^{\beta}S^{\zeta} - 1$. These equations of channel incision process at reach-scale further become the fundamental equations in Landscape evaluation models (LEMs) to understand landscape dynamics in response to external controls.

The general form of transient solution to Eq. 11 can be achieved using method of characteristics (Royden and Taylor 2013, Appendix A) and can be written in the following integral form (for $\zeta = 1$):

$$h(t, x) = \int_{t-\tau(x)}^t U[t', \tau^{-1}(\tau(x) - t + t')] dt' \quad (13)$$

where t' is an integration variable. $\tau(x)$ is the response time for any perturbation (e.g., surface uplift) and can be defined as:

$$\tau(x) = \int_0^x \frac{dx'}{Kx'^m} \quad (14)$$

where x' is another integration variable. Equations 13 and 14 can be used to get the tectonic or climate information from river long profile (Goren 2016) using linear inversion technique.

Exponential Function

The exponential equation has great utility in mathematical modeling since both its integration and differentiation gives the same original form. In ESP studies, elevation (h) of topography is often related to horizontal distance (x) as:

$$h(x) = h_0 \exp(-ax) \quad (15)$$

where h_0 is the elevation of topographic ridge and a is a decay constant. The exponential function is also a solution of the following differential equation for eroding topography:

$$\frac{dh}{dx} = c - ah \quad (16)$$

River long profile has been modeled by exponential functions to infer the control of sediment transport process, geology, and climate on long profile evolution (Sonam and Jain 2018). Exponential functions are also prevalent in the morphometric analyses of the drainage network (Strahler 1957).

The reciprocal of the exponential function is the logarithmic function. The logarithmic function is famous in the field of ESP in the form of Hack profile (Hack 1973), which can be derived by assuming a gradual downstream drop in elevation along a river profile:

$$h = h_u + c \log\left(\frac{x_u}{x}\right) \quad (17)$$

where x_u and h_u are the distance of channel head from drainage divide and channel head elevation, respectively. c is a proportionality constant.

Power-Law Function

Power-law successfully captures the very essence of the structure of a natural system's nonlinear behavior. It is widely used to characterize the statistical property of any natural system and can be regarded as a first-hand proof of self-organized criticality (Van De Wiel and Coulthard 2010), which widely governs the dynamic processes in nature.

Power-law is also a quintessential example of a fat-tailed distribution, which can be observed for most of the extreme phenomena, such as frequency of earthquake (Bak and Tang 1989) or flood (Malamud and Turcotte 2006), among other natural hazards. Power-law functions are very common in fluvial geomorphology. They arise in drainage basin characteristics, such as Hack's law (Hack 1957), which relates the upstream area and length of a basin and indicates the evolutionary pattern of a river basin:

$$L = K_H A^H \quad (18)$$

One of the other important examples in fluvial geomorphology is the relation between slope and upstream area of an equilibrated landscape (Wobus et al. 2006):

$$S = k_s A^{-\theta} \quad (19)$$

where k_s and θ are channel steepness and concavity, respectively.

Fractals in ESP

Coupled interactions of governing factors lead to complex natural forms, which can be mathematically represented as fractal objects, which shows statistical self-similarity at different scales of observation. These fractal objects or forms can then be characterized with fractal dimension. Estimation of the fractal dimension of natural objects utilizes the power-law dependence of some basic physical properties of the objects (e.g., length of a coastline) on the scale.

$$l \propto r^{1-d} \quad (20)$$

where l is the total length of a fractal object (coastline, Mandelbrot 1967) and r is the scale of observation. The slope of this line on a log-log scale gives us the fractal dimension, d . Recent geomorphological studies have related the fractal dimension of the topography to governing controls, such as tectonics, climate, and lithology (e.g., Sahoo et al. 2020).

Multifractals, on the other hand, can be regarded as objects comprising a union of subsets, each characterized by different scaling exponent (Berkowitz and Hadad 1997). An appropriate description of multifractal nature of sets of any measure is the singularity spectrum $f(\alpha)$ (Halsey et al. 1986). The width of this spectrum has been used in literature to interpret the governing factors in landscape and drainage network evolution (e.g., Dutta 2017).

Matrices

The primary spatial data often used in any ESP analysis is the digital elevation model (DEM), which is a synthetic model of the earth's landscape in the form of matrices. Each grid (pixel) of the DEM contains the average elevation of the corresponding ground pixel of a certain area depending on the resolution of the DEM product. ESP studies use DEMs to estimate transport of flux across the landscape, for which spatial relation of a grid to its neighborhood is of primary importance. The matrix form of DEM provides the opportunity to avail the powerful techniques of linear algebra for modeling. For instance, the upstream contributing area is a proxy for the flux at any cell of the DEM and can be estimated using the following relation in matrix form (Schwanghart and Kuhn 2010):

$$a = [I - M^T]^{-1} w(0) \quad (21)$$

where a is the upstream contributing area vector, I is the identity matrix, M^T is the transpose of the flow direction or transfer matrix, which is slope-dependent, and $w(0)$ is the initial amount of water in each cell. Similarly, set theory-based morphological operations (e.g., erosion, dilation), which contains simple linear operation between images (2-D sets) are widely used for feature extraction from DEM. For example, river networks can be extracted from DEM using skeletonization technique, and can be mathematically defined as follows (Sagar et al. 2000):

$$CH(I) = \bigcup_{k=1}^{i-1} \left[\bigcup_{j=0}^J CH_m(A_k) / A_{k+1} \right] \quad (22a)$$

$$CH_j(A) = [A \ominus B_j] / [(A \ominus B_j) \ominus B] \oplus B \quad (22b)$$

where $CH(I)$ represents the river channel network corresponding to gray scale image (DEM), I, j is the size of the structuring element B , k is the number of binary sets, A , derived from I using thresholding operation. Sagar et al. (2000) can be referred for the definitions of the binary operations used in Eqs. 22a and 22b.

Further, in ESP studies, we have a huge set of output, in terms of elevation, sediment load, the chemical signature of sediment, etc. Hence, we mostly deal with inverse problems to get an estimate of model parameters of the governing equations of such geomorphic entities, such as source, diffusivity, and BC. These inverse problems also make use of principles of linear algebra. The governing equations for any ESP problem can be generally written as a system of linear equations, which in matrix form generally renders itself as follows:

$$d = Am \quad (23)$$

Here, d is a data vector to study effects and A represents the causal connection between cause (m) and effect (d). In inverse problems, we solve this system of linear equations. The model parameters (m) can be tectonic uplift rate in the context of landscape evolution (Goren et al. 2014), chemical erosion rate in the context of sediment source fingerprinting (Tripathy and Singh 2010), and so on. We can minimize both the error (inherent in data) and the length of the solution vectors (penalty) for a near-singular matrix A . With an apriori set of values for the parameters (m_p) and a penalty factor (δ^2), the solution becomes (Tarantola 2005):

$$m = m_p + (AA^T + \delta^2 I)^{-1} A^T (d - Am_p) \quad (24)$$

Statistical Approaches in ESP

Statistics in ESP is primarily used for regression analysis, sensitivity analysis, uncertainties estimation, among other types of quantification of geomorphological processes. Statistical measures (e.g., central measures or dispersion) are also often used to characterize ESP, as well as the landscape features. Additionally, in modern-day landscape evolution models, there is scope to use stochastic time-varying forcings (climate, tectonics), which can be drawn from a characteristic probability density function (pdf) for climate forcings [rain-fall intensity (P), storm duration (T_r), and interstorm period (T_b)] (Tucker and Bras 2000):

$$f(P) = \frac{1}{\langle P \rangle} e^{-P/\langle P \rangle} \quad (25a)$$

$$f(T_r) = \frac{1}{\langle T_r \rangle} e^{-T_r/\langle T_r \rangle} \quad (25b)$$

$$f(T_b) = \frac{1}{\langle T_b \rangle} e^{-T_b/\langle T_b \rangle} \quad (25c)$$

where $\langle - \rangle$ represents long-term average of a stochastic variable. Central limit theorem (CLT) constitutes a fundamental component of large-sample statistics. State-of-art resampling techniques, such as Monte-Carlo or bootstrap techniques, make use of the CLT and are widely used for error propagation and uncertainty analysis (Blaauw 2010) in ESP models.

Numerical Methods in ESP

Numerical methods enable us to solve evolutionary problems, usually comprising of multiple differential equations, as a set of algebraic equations for a discrete set of points in space and time. These methods discretize the time (and space in case of PDE) over which we try to solve our problems into different nodes. Then it uses a numerical approximation of differentials (e.g., Newton's Difference quotient) to solve the governing equations for each of the nodes.

Finite Difference (FD) method is one of the easiest to use in family of techniques to solve any differential equation. For instance, in order to solve a linear advection-diffusion equation (Eq. 3 in 1-D), we can use an explicit central difference scheme as follows:

$$\frac{h_i^{j+1} - h_i^j}{\Delta t} = D \frac{h_{i+1}^j - 2h_i^j + h_{i-1}^j}{\Delta x^2} - K \frac{h_{i+1}^j - h_i^j}{\Delta x} \quad (26)$$

where h^{j+1} depends on h^j . Here, i and j are the spatial and temporal indices, respectively. Δx and Δt represent the grid spacing and the time step of the numerical scheme. There is also an implicit scheme in FD method with a distinct advantage of unconditional stability (Perron 2011).

Finite Volume (FV) method is another technique being widely used in landscape evolution models (Tucker et al. 2001). In the FV method, the whole domain is divided into cells, and the basic continuity equation (without any source or uplift for our example) is integrated over the surface area of a cell as follows:

$$\iint_A \frac{\partial h}{\partial t} dA = - \iint_a (\nabla \cdot q_s) dA \quad (27)$$

Using Gauss Divergence theorem and integrating the first term as an area-average, this equation transforms into

$$A_i \frac{\partial \bar{h}_i}{\partial t} = \oint_p (q_s \cdot \hat{n}) dp \quad (28)$$

Here, A_i is the area of a cell, p represents position along the perimeter of the cell, and $\hat{n}$ is a unit vector normal to the perimeter and pointing outward and $\bar{h}_i$ is the average elevation of the cell. Both time derivative and surface integrals for a diffusion problem are then approximated as (Tucker et al. 2001):

$$\frac{h_i^{j+1} - h_i^j}{\Delta t} = \frac{D}{A_i} \sum_{\alpha=1}^{np} \lambda_{i\alpha} \frac{h_\alpha^j - h_i^j}{L_{i\alpha}} \quad (29)$$

where A_i is the area of a Voronoi cell, the sum is over all the np points adjacent to cell i , the ratio inside the sum represents the slope of a segment (between i and one of the neighbors α), and $\lambda_{i\alpha}$ is the length of the corresponding Voronoi edge. The FV numerical scheme further provides the base to LANDLAB, a python-based landscape evolution model, which is being used extensively in teaching and research (Hobley et al. 2017).

Machine Learning Application in ESP

ESP community is witnessing a paradigm shift in the past couple of decades caused by the big data pool generated from the rapid advancement in the field of remote sensing techniques. The rapidly evolving field of machine learning (ML) is tipped to play a vital role in the effort to extract useful information from the big data. ML application in ESP studies have been applied most notably in landslide hazard mapping, soil classification, and landform classification (e.g., Bergen et al. 2019). For instance, artificial neural network (ANN) is widely used for landslide susceptibility mapping (Bragagnolo et al. 2020). The mathematics behind ML techniques primarily constitutes linear algebra and differential calculus.

A unique challenge in ML for ESP studies is that ESP is governed by physical laws, and the resulting events are highly correlated at different scales in both space and time. A recent review by Reichstein et al. (2019) highlighted this challenge

and suggested that these novel aspects of ESP problems should be used as part of deep learning to gain further process understanding of Earth system science problems.

Conclusions

Mathematical concepts provide important tools to analyze the process interactions and feedback at different scales across various geomorphic agents. It also helps to integrate ESPs driven by different geomorphic agents. Application of mathematical methodologies has not only quantitatively expressed the patterns of landscape/landforms but also provided new insights about cause–effect relationships. These methods are now fundamental to understand the complex and nonlinear behavior of geomorphic systems.

Definition

The Earth system refers to an organic whole composed of the atmosphere, hydrosphere, geosphere (lithosphere, mantle and Earth core), and biosphere (including human beings). Earth system science (ESS) is to study the mechanism of the interaction between these subsystems of the Earth system, the law of the change of the Earth system and the mechanism of controlling these changes, so as to establish a scientific basis for the prediction of global environmental change and provide a basis for the scientific management of the Earth system. The space scope of Earth system science research ranges from the center of the Earth to the outer space of the Earth, and the time scale ranges from hundreds of years to millions of years.

Goal of Earth System Science

The research purpose of Earth system science is to understand the processes involved in the Earth system, the connections, and interactions between various components, maintain sufficient supply of natural resources, reduce geological disasters, regulate global environmental changes and minimize hazards, and obtain a scientific understanding of the whole Earth system on a global scale.

Human beings have become one of the forces that change the topography, geochemistry, and life evolution on a global scale. Taking human beings as an independent sphere, we should strengthen the research on the interaction between geosphere, biosphere, and anthroposphere and reveal the interaction between the Earth system, including the Earth's spheres. This marks a major change in the research object, guiding theory and research methods of Earth Science, paying more attention to the research of man-Earth relationship, highlighting the characteristics and evolution of the Earth system, adjusting man-Earth relationship, and promoting man-Earth harmony (Steffen 2004).

History of Earth System Science

Earth system science has experienced four stages: the embryonic stage before the 1970s, the discipline establishment stage in the 1980s, the global stage in the early twenty-first century, and the contemporary development after 2015.

In the middle of the twentieth century, geoscience began to be internationalized. Marked by the International Geophysical Year (IGY) from 1957 to 1958, this unprecedented research integrated the research works of 67 countries and improved the comprehensive understanding of the Earth's sphere system. The important achievement of this stage is the GAIA hypothesis put forward by James Lovelock in 1972, which has produced a new way of thinking about the Earth: recognizing the important impact of biota on the global environment and the importance of correlation and mutual feedback among the main components of the Earth system.

The NASA's Earth System Science Committee was established in 1983 (National Research Council 1986) and published the report "Earth System Science" in 1988 (NASA Advisory Council 1988). It formally put forward the concept of Earth system science and promoted the development of ESS through observation, modeling, and process research and supported Earth observation system satellites and related research. The research project led by NASA had developed the Bretherton structure diagram, which was the first system dynamics display of the Earth system. Through a series of complex external conditions and feedback, it coupled the physical climate system with the biogeochemical cycle, visualizing the physical, chemical, and biological processes connecting the interaction of various components of the Earth system and to recognize that human activities were an important driving force for system change (Shikazono 2009; Cornell et al. 2012).

From the 1990s to the early twenty-first century, the global research system supported by international programs such as World Climate Research Programme (WCRP), International Geosphere Biosphere Program (IGBP), International Biodiversity Program (DIVERSITAS), and International Human Dimensions Program on Global Environmental Change (IHDP), provided a "workspace" for the cooperation of scientists from different disciplines around the world, which was very important to the development of ESS.

After 2015, ESS has been relatively mature and began to carry out major institutional restructuring and interdisciplinary research on the basis of higher-level integration. IGBP, IHDP, and DIVERSITAS were merged into the new plan "Future Earth" in 2015, aiming to accelerate the transformation to global sustainability research through innovation (Steffen et al. 2020; Castree 2021).

Research Tasks of Earth System Science

1. Observation of Earth system phenomena and accumulation of Earth system multisource and multimodal data.
2. Analyze and interpret the observation data, and establish quantitative relationship among physical phenomena, chemical phenomena, and biological activities.
3. Establish Earth system conceptual model and numerical model.
4. Verify the model and use it to make predictions and forecasts of future trends.

New Concepts in Earth System Science

Since the beginning of the twenty-first century, with the development of Earth observation and detection technology, the concept of Earth system has been strengthened, which has promoted the intersection and integration of multi-disciplines. The development and evolution of Earth system science have also spawned a series of new concepts. The concept of geological diversity is formed on the macro scale, the concept of Anthropocene is formed on the time scale, the concept of critical zone of the Earth is formed on the spatial scale, and the concept of tipping element is formed on the element scale. These concepts promote the development of Earth system science in depth.

1. Geological diversity: one of the important theoretical cornerstones of Earth system science. Geological diversity refers to the diversity of geological (rocks, minerals, fossils), geomorphology (topography, physical process), soil, hydrology, sediment, and other element characteristics and the combination and process of elements. Geological diversity, biological diversity, climate diversity, and marine diversity constitute the basis of sustainable development. Geological diversity and biodiversity constitute natural capital, bring ecosystem services and geological system services to mankind, and jointly supply and maintain the whole natural system.
2. Anthropocene: the key time scale of Earth system science research. In view of the fact that human activities have become a very active geological force, Dutch atmospheric chemist Paul Kruzen and ecologist Eugene Stoermer jointly put forward the concept of “Anthropocene” in 2000 and regarded it as a geological Holocene period that was replaced by Pleistocene and Holocene. Once the concept of Anthropocene was put forward, it was widely recognized by the Earth science community. Geoscientists have discussed the starting point of the Anthropocene.

There are four main understandings: (a) the lower limit of the original Holocene; (b) in the early Holocene, the lower limit was pushed to thousands of years ago; (c) the beginning of the industrial revolution, that is, the second half of the eighteenth century; (d) the middle of the twentieth century, that is, the time when mankind’s first atomic bomb exploded in 1945. On May 21, 2018, after voting, it was determined that the starting point of Anthropocene was set in the middle of the twentieth century.

3. Earth critical zone: the entry point of Earth system science research. The concept of Earth critical zone was first seen in the strategic report of the National Research Council on Opportunities for Basic Research in Geosciences in 2001. It refers to the zone where the near surface environment in the shallow lithosphere intersects and interacts with the hydrosphere, atmosphere, and biosphere. It takes the vegetation canopy and deep underground aquifer as the upper and lower interfaces (affected by altitude and landform). It is also a composite space for the interaction between chemical processes of Earth materials and biological activities. Earth critical zone requires comprehensive observation and research of geology, geochemistry, hydrology, pedology, biology, geomorphology, and other disciplines, so as to understand the global and millennium span human adaptability to environmental changes. The National Science Foundation of the United States had set up 10 observation stations, whose observation contents include external geological processes in different evolution stages, weathering crust and soil formation, biological and microbial activities, aquifer and surface water, energy and material processes, landscape evolution, and water and carbon cycle. The concept of Earth critical zone has created conditions for the Earth system to scientifically solve major geological events in local areas (important water resources areas, geological fragile areas and important urban areas). Through the geological mapping, monitoring, modeling, and prediction of the Earth critical zone, the formation and evolution law of the Earth critical zone are revealed, and then the protection and restoration scheme of the ecological environment is put forward.
4. Tipping elements: nonlinear characteristics of the Earth system. Tipping elements refer to subsystems or system elements that can change fundamentally in the Earth system, such as global climate warming and environmental change caused by human activities. Arctic sea ice and Greenland ice sheet are critical elements. Tipping element is an important concept to describe the characteristics of the Earth system, which shows that the Earth system has strong characteristics of nonlinearity, complexity, and openness (NASEM 2021).

Information Processing and Expression in Earth System Science

The Earth is a complex giant system. The span of time and space varies greatly. Only by using high-speed computers can we simulate some unobservable phenomena. Using data mining technology, we will be able to better understand and analyze the observed massive data and find out the laws and knowledge. Scientific computing can break through the limitations of experimental and theoretical science. Modeling and simulation can explore the collected data about the Earth more deeply.

In the era of big data and artificial intelligence, Earth system data, information system platform, and Earth system numerical model are the infrastructure of Earth system science research. Digital Earth is regarded as an effective carrier and platform of Earth big data, which can provide a series of technologies, methods, and integrated environment for Earth system scientific research (Reichstein et al. 2019; Irrgang et al. 2021).

Digital Earth is the digital expression of Earth System Science, which will be conducive to the development from the qualitative description of natural phenomena to quantification. Digital Earth takes the Earth system as the prototype, the Earth coordinate as the reference system, and the Earth system science, information science, and computing science as the theoretical basis and realizes the integration of a series of prototypes, mathematical models, physical models, mechanical models, information models, and computer models at different levels. At the same time, with the support of Earth observation and network new technology, it builds the fusion of multi-resolution, massive data, and various data and uses multimedia and simulation virtual technology for multidimensional expression based on a digital, networked, intelligent, and visual technology system, so as to understand the information process involved in the whole Earth system and pay special attention to the law of information connection and interaction between various spheres of the Earth system. The main research contents include digital Earth prototype, theoretical basis of Earth system field, digital Earth material model, digital geodynamics model, digital Earth mathematical model, digital Earth information model, digital Earth information acquisition technology, digital geospatial information infrastructure, and digital Earth engineering.

Next Generation of Earth System Science

In May 2021, the European Commission announced that it would fund two new Earth system model (ESM) development projects through the “Horizon 2020” program to further improve the expression of the Earth system model on key processes and coupling systems and improve the simulation, prediction, and prediction ability of climate models.

In 2021, National Academies of Sciences, Engineering, and Medicine, USA, released the report “Next Generation Earth Systems Science at the National Science Foundation”. The main contents include (1) at present, human technologies and activities in economic development and resource utilization have begun to compete with and even exceed the scale of natural processes in driving the process of the Earth system. Our understanding of some key issues has been slow, such as the rapid changes in the Earth’s natural systems, the extent of human impact on them, the impact of the Earth’s natural systems on the sustainability and resilience of humans and ecosystems, and the effectiveness of different ways to meet these challenges; (2) The relationship between nature and society is the core of many complex problems faced by society and the Earth. It is necessary to recognize the multi-directional relationship between these natural and social subsystems in the context of science and technology. Integrated research provides a method to develop comprehensive science, construct research problems from the perspective of social problems, and integrate the knowledge and methods from nature, society, computing, and engineering science from the beginning; (3) Infrastructure such as observation, computing, and modeling must work together to support the integration of Earth system science. Observation and monitoring reveal changes in the Earth system. The model representing the natural and social system processes and their interactions of the whole Earth system absorbs data from a variety of sources. Computing provides a framework for integrating complex parts of Earth system science, supporting data collection and analysis, generating predictions, and interpreting model results (NASSEM, 2021).

Conclusions

Earth system science is a new view of the earth and a revolutionary change of human view of the earth. This change is reflected in the following five aspects:

1. The Earth is an organic system, which can be understood from the spheres and its interactions of the earth.
2. The earth is a symbiotic community of human and nature, full of complex changes.
3. Humans are becoming the driving force of global change.
4. Mission on sustainable development: it is impossible for human beings to transcend the limitation of the Earth’s living space and available resources, and let alone change the law of the earth system itself. Mankind is duty-bound to manage the earth.
5. New methods and technologies based on big data and artificial intelligence provide a new research paradigm for earth system science.

Earthquake Complexity

William I. Newman

Departments of Earth, Planetary, & Space Sciences, Physics & Astronomy, and Mathematics, University of California, Los Angeles, CA, USA

Definition

Earthquakes belong to a class of phenomena referred to as complex where the hallmark of complexity is the interplay of a variety of nonlinear factors. These factors embrace behaviors such as self-organization, scaling and fractal behavior, chaos in high degree-of-freedom systems, including sensitivity to initial conditions, and the emergence of hierarchical networks wherein these factors can mutually influence each other, even in the presence of extraordinary heterogeneity.

Introduction

Earthquakes continue to pose catastrophic risks to major population centers. Historically, they have had devastating

effects with the most extreme events taking place in Shangxi, China (designated as 1556 M8.0 Shangxi earthquake), which possibly killed over 800,000, to the twentieth century with the Tangshan, China, event (designated as 1976 M7.6 Tangshan earthquake) where estimates of fatalities range from over 240,000 to as many as 650,000. During this century, the 2004 Indian Ocean earthquake and tsunami (designated 2004 M9.1 Sumatra-Andaman earthquake), as well as the 2010 Haitian earthquakes, have each taken approximately 200,000 lives, with many more lost due to the unavailability of medical assistance and proper sanitation and hygiene. The heightened awareness of the earthquake threat has become especially prominent in assessments of potential seismic catastrophes in both northern and southern California (along the San Andreas Fault), the Pacific Northwest of the United States and Canada (Juan de Fuca Plate, commonly called the Cascadia subduction zone), and in Japan (Tōkai region between Nagoya and Tokyo). Taken together, these events and our expanding knowledge of the earthquake mechanism gave rise to the hope that earthquakes of substantial size could be predicted with some specificity regarding their magnitude, location, and time. For reasons that we shall discuss, these goals were quickly dashed owing to their failure to make reliable predictions. It is important to note, quite apart from the attendant scientific and engineering issues, that the prediction of major events that do not occur and, even more significantly, the failure to predict major destructive events have dramatic legal–political–social outcomes. In the aftermath of the failure to develop reliable prediction techniques, there is now emerging a renewed hope in forecasting such events using pattern recognition schemes, possibly in conjunction with machine intelligence. In contrast with prediction, earthquake forecasting has a limited capacity to provide a probability-based assessment of seismic hazards in relatively large spatial and temporal domains, for instance, that southern California might expect a significant earthquake (magnitude 6.7 or greater) during the coming 30 years of 59%, with a 37% chance of a magnitude 7.5 or greater event during that time window. An excellent nontechnical overview of our general understanding of earthquake phenomenology and its inherently unpredictable nature may be found in the semi-popular books by Hough (2009) and Jones (2019). These estimates undergo continual updating and revision, but it is unlikely that we will ever be able to predict events in the way that we routinely predict the weather.

Ironically, we sought to improve the quality of local or synoptic weather forecasting using numerical weather prediction models (Browning 1980) in conjunction with routine updates of prevailing conditions via “data assimilation” techniques. This has given rise to the concept of “nowcasting,” literally the amalgamation of “now” with “forecasting,” the term coined by Browning (1980). Very short or mesoscale prediction over periods of 2 hours is a methodology accepted

by the World Meteorological Society, while the blending of econometric data with statistical models has become popular in economics as a modality for assessing the state of the economy. In a similar fashion, geophysicists such as Rundle et al. (2021) seek to blend existing observations of long-term trends with potentially observable changes in the (local) state of the Earth employing a variety of possible “precursors,” manifestations that likely can be causally connected with the underlying physics of rock fracture. The application of new methodologies arising from machine learning, data mining over complex hierarchical networks, and artificial intelligence could lead to the ability to obtain improved estimates of short-term, on a scale of hours to days, major seismic events. As we will observe later, earthquakes and the fault networks on which they occur are “complex systems” and, like other complex systems (Malik and Ozturk 2020) – including the brain, human society, and infrastructure systems – experience events that are rare in frequency but can have catastrophic consequences. The complex system framework provides both new challenges and opportunities.

Finally, there are some aspects of seismic wave propagation that could be exploited by “warning systems” that utilize the difference in propagation velocities of the first-to-arrive P (for primary or compression) waves, and the much more destructive but significantly later-to-arrive S (for secondary or shear) waves. As an illustration, P waves travel with velocities ranging from 5 to 8 km/s, depending on rock type, in contrast with S waves whose seismic velocities are typically 60% of P waves. In essence, the initial detection of a P wave with potentially much larger S wave to come could allow major infrastructure components, such as electrical power to be switched to emergency generators while natural gas supplies would be terminated to reduce the risk of fire, as well as other mitigation actions.

The Implausibility of Earthquake Prediction

The focus of this chapter will be on understanding why prediction is impossible while forecasting has limited value. The immediate and profound implication here is that construction standards in earthquake-prone areas must of necessity be increased in homes, businesses, schools, hospitals, and other life-critical agencies. They must be designed, equipped, and prepared to remain resilient in their response to earthquakes and quickly recover in their aftermath (Hough 2009; Jones 2019). While there are many other issues pertaining to earthquakes and their effects, we will provide a glimpse into the nature of the uncertainties underlying the earthquake mechanism via the 1906 San Francisco earthquake. We will observe how they transcend simple notions of chaotic behavior and require that seismic events be regarded as illustrations of dynamic complexity. The implications of that paradigm

shift are profound. Our approach is to focus on an audience trained in applied mathematics, including some application to the geosciences, but having only modest exposure to ideas emergent from geology as well as new concepts arising from what is presently called complexity theory. A good introduction to the essential aspects of complexity can be found in the semi-popular books by Waldrop (1993) and Mitchell (2009). Unlike many other arenas in the mathematical geosciences, such as geophysical fluid dynamics, the nature of earthquake faults and their distribution and associated phenomenology are not known a priori. Friction parameters and stress distributions on faults are known to some degree based on seismicity patterns, stress drops, and slip orientation identification. Hence, modeling such phenomena is only possible in a very approximate way through a variety of phenomenological models arising from empirical observations of earthquake events. However, they are not known well enough to be used as reliable initial conditions for simulations in the context of prediction.

With these caveats, let us now consider some of the phenomenological aspects that characterize regions that are particularly prone to earthquakes as well as introduce some of the nomenclature, before proceeding to explore global aspects of such behaviors. Earthquakes refer to the shaking that is experienced intermittently in such localities, but global factors underscore their selection. The shaking is often described by its magnitude, which, loosely speaking, is a logarithmic measure of the energy released in the process, although there are better quantitative descriptors such as the seismic moment. The magnitude of events was invented by Gutenberg and Richter in 1958, who observed a scaling law relating the magnitude to the frequency of such events, a theme we will return to later, inasmuch as it is manifestly universal. (Ironically, Richter has been quoted as saying that “only fools and charlatans” predict earthquakes – a litany of false predictions and failure to predict are a fixture of contemporary life.) The cause of earthquakes is generally recurrent with the time interval between events and the energy released being variable. Qualitatively speaking, they are related to fracture or rupture of earth materials beginning at a location referred to as the hypocenter at approximately 10–20 km depth; the projection of the hypocenter on the Earth’s surface is referred to as the epicenter. For example, suppose a given region with an area of several hundred square kilometers experiences a magnitude 4 earthquake approximately once a month, then it will experience magnitude 5 being 10 times less frequently, and so on. Similarly, the energy released in a magnitude 5 event is approximately 30 times greater, more accurately $\sqrt{1000}$, than a magnitude 4 event. While the amplitude of earth motion varies with respect to the magnitude M for low-magnitude events, say, $M \leq 4$, the amplitude of body-waves will saturate as events begin to exceed $M \approx 6.5$ but shaking quantitatively

observed as body waves will be sustained for longer intervals of time than smaller events. Meanwhile, the shaking associated with surface waves saturates at $M \approx 8.0$ and above. We qualitatively distinguish among earthquakes as being foreshocks, main shocks, and aftershocks – each of these designations is largely artificial inasmuch as they present the same qualitative seismic waveform and refer solely to their respective magnitudes. The main shock is preceded by a foreshock 30% of the time – and this underscores an underlying limitation to prediction: there is no a priori way to distinguish the category in which a given event occurs. Most of the time, around 70% of events, an earthquake is a “main” shock, but 30% of the time that earthquake is a premonitor of a larger one to come. Meanwhile, most shocks are followed by lower-magnitude aftershocks with a diminishing rate of occurrence (Omori’s law) and also display a drop in magnitude of approximately 1–1.2 (Bath’s law). Having noted the energetic character of destructive earthquakes, it is noteworthy that the January 17, 1994, Northridge, CA, earthquake with a magnitude of 6.7 released more energy than a 5 megaton bomb, while the Sumatra-Andaman earthquake and tsunami of December 26, 2004, with a magnitude of approximately 9.1 released 1000 times more energy than the largest hydrogen bombs detonated during the depths of the cold war. Associated with the initiation of an earthquake with the local failure of rock materials at depth, a variety of related phenomena can occur. For example, gases associated with the geochemical synthesis of those materials can be trapped during their formation in the interstices between grains in rocks but are released when those materials are subject to extreme stress and the gases released might be measurable. Similarly, the changes in the rock environment can influence its electrical resistivity. The failure of rock materials subject to micro-cracking could result in ultrasonic emission of sound and possibly other phenomena. This in turn has been related to observations of various mammals and even fish manifesting “skittish” behavior prior to substantial seismic events. The operative question, however, is whether any of these or possible other physical–chemical process provide a set of precursory phenomena that regularly and reliably serve as prognosticators of impending earthquake activity. The answer, sadly, is no – though certain precursors appear to occur about 30% of the time – the books by Hough (2009) and Jones (2019) offer good resources accessible to lay audiences into the limitations of prediction.

Pervasive Patterns Consistent with Complexity

Let us now turn our attention to the global distribution of earthquake events and how these must be incorporated into developing a mechanistic understanding of the earthquake process and its multifactorial manifestations, and the

fundamental limitations to their prediction. Prior to the 1906 San Francisco earthquake, the prevailing view of the processes associated with the formation of the Earth’s surface and topography arose from ideas relating to the formation of solar system bodies through a process of gravitational accretion of granular and icy materials present in the primitive solar nebula. It was widely accepted then that the collision of such materials and their subsequent gravitational accretion produced the planets that slowly cooled, leaving a wrinkled surface, metaphorically like a baked apple taken out of an oven. Meanwhile, the accumulation of global insights into the distribution of the Earth’s continents and a variety of other inherently geological features led by the pioneering work of Wegener (1923) and others led to the establishment of the paradigms of continental drift and of plate tectonics. The premier feature of plate tectonics is evident from Fig. 1, which describes the global seismicity of the Earth, 1900–2007 (USGS Scientific Investigations Map 3064, public domain), providing a comprehensive overview of great earthquakes (M8.0 and larger). Recalling our reference to the notion of a cooling primordial Earth, we appreciate that the radioactive decay of heavy isotopes in its deep interior preserves a molten liquid state below its crust and mantle. This material in turn is undergoing convection at a rate of several centimeters per year, propelling the cooler-solidified materials toward the surface where they collect and form “tectonic plates.” The critical feature here is that the locus of these epicenters identifies the major convergent tectonic plate boundaries, where the oceanic and continental crust can collide and are forcibly driven together. Depending on location, those contact points can be associated at this time with the plunging of some plates below others, a process known as “subduction” (e.g., the Indian and Eurasian plates and the formation of the Himalayas via dip-slip events) or with shearing resisted by friction (e.g., the San Andreas fault in the Americas with strike-slip events). The East African Rift System, as well as the North and East Anatolian Faults, together with the western edge of the Pacific Plate, including the 2011 Tohoku earthquake and tsunami, has had a profound influence in human historical terms. While most of the relative motion observed on the plates is in the horizontal direction, crudely 10% is in the vertical, contributing to the rise, for example, of the Sierra Nevada mountain range by a few tens of centimeters every century. Approximately 70% of seismic events – as well as volcanic events that are also associated with tectonic plate boundaries and very hot sources of molten rock or magma residing below some descending plates – are associated with such convergent boundaries. Seismic events that take place under the Pacific, especially, can produce tsunamis (the term “tidal wave” is a misnomer), particularly if the relative motion of the two plates has a substantial vertical component. The remaining 30% of seismic events are associated with so-called “hot spots,” including, for

Earthquake Complexity, Fig. 1 Global seismicity 1900–2007 $M \geq 8.0$ with filled colored circles designating earthquake events with hypocenters ranging from 0–69 km (red), 70–299 km (green), and 300–700 km (blue).

The diameter of each circle designates the moment magnitude (M_w) with larger circles identifying larger events.

example, the Hawaiian Islands, which were formed by the injection of magmatic materials through the overlying oceanic crust to form a new land mass, and an even smaller number of “intra-plate” events, likely associated once again with deep-rooted convective cells, such as that which produced the four New Madrid earthquakes of 1811–1812 with $M \approx 7.2$ – 8.2 and resulted in the displacement of the Mississippi River by about 2 kilometers. Each of these different types of earthquake events displays distinct characteristics and is even less amenable to prediction.

The preceding discussion highlighted the remarkably complicated character of global tectonics driven by fluid motion in the Earth’s mantle. While there are nearly a dozen major plates and many more smaller plates, their dynamic interactions are substantially more complicated. While the mass media focuses on the nature of the San Andreas Fault and the concerns that it raises among residents of Los Angeles and San Francisco, the situation is geologically highly intricate, as shown in the map displaying a complex hierarchical network of fault ensembles and its presentation of California seismicity (Fig. 2). Indeed, we observe that California’s earthquake faults constitute a highly irregular yet hierarchical interlocking network, much of it concealed below the Earth’s surface. There is a significant literature addressing the geometric complexity of fault networks, demonstrating that they satisfy through their scaling statistics the nature of a fractal. See the textbook by Turcotte (Turcotte 1997) for an

introduction to issues attendant to fractals and chaos in geological settings. We will return to the theme of complexity momentarily.

Finally, we wish to assemble in a more quantitative way the statistical behavior observed in the energy released, through the proxy of earthquake magnitudes. Then, we will explore the statistical distribution describing the likelihood that a given event can be associated with specified energy via its logarithm (the magnitude), the so-called Gutenberg–Richter law, and other earthquake-related scaling laws such as Omori’s law and Bath’s law mentioned earlier. This figure reveals that the number N of events larger than a magnitude M satisfies the empirical Gutenberg–Richter law in the form

$$\log_{10} N = -bM + \log_{10} \dot{a} \quad (1)$$

where $\dot{a}$ and b are constants. While the rate $\dot{a}$ depends upon the geographic region and area considered among other factors, the value of b appears to be slightly above 1 without exception. We show this in the following plot, where we have normalized the number count and fit the data using the prevailing standard using the numbers of events above a given magnitude per year. We observe for this global dataset that a “b-value” of approximately 1.025 emerges. Events above magnitude 7.5 fall in frequency below the expression shown, likely because the largest events are associated with ruptures that extend to significant depths below the surface

Earthquake Complexity, Fig. 2 USGS map of the principal faults in California demonstrating the interplay between different fault zones over geological time. This kind of topographical character is an indicator of

fractal geometry. Certain faults displayed could be relics of faults that existed in prior geological periods as the western or leading edge of the North American Plate migrated away from the mid-Atlantic ridge

where temperatures are much higher and the rocks are much more viscoelastic than at the surface. We noted the statistical uniformity of large seismic events. Paradoxically, this unvarying behavior persists despite a remarkable degree of heterogeneity in the rock compositional types, mechanical

properties, and geometries present along the faults that make up the “ring of fire,” the pattern evident in the epicenters that reside on the periphery of the Pacific Ocean. The added irony here is that universal scaling laws are observed statistically, just as we see in fully developed isotropic turbulence in fluid

dynamics. Nevertheless, nonuniformity and heterogeneity prevail, thereby compounding the challenge of developing any reliable predictive capacity.

The 1906 San Francisco Earthquake: Unequivocally Unpredictable

Our understanding of the earthquake mechanism underwent a fundamental advance in the wake of the October 18, 1906, San Francisco earthquake, the first major earthquake to strike a large population center in the twentieth century. An important geographic aspect of the “ring of fire” is that it resides in coastal areas that are very attractive for human habitation with some of the world’s greatest cities exposed to risk from major earthquakes and their associated tsunamis. With an estimated magnitude of $\approx 7.9 \pm 0.2$ and a maximum Mercalli intensity of XI (a semi-quantitative metric designated by Roman numerals and designating the degree of shaking affecting structures), more than 3000 people died and more than 80% of the city was destroyed. This event occurred long before the ring of fire and plate tectonics came to be widely recognized and accepted in the 1970s. Nevertheless, the State Earthquake Investigation Commission issued a remarkably prescient and comprehensive 451-page report including 146 photographic plates. This monumental study documented the highly varied geological setting and manifestations of the earthquake that were directly observable over the >450 km extent of the rupture. Evidently, the region affected originated at ≈ 8 km depth below part of the feature called at the time the “San Andreas rift.” Geologists also referred to it as a fault, having no comprehension of how it came to be nor especially how it was part of a global-scale phenomenon. The report describes the geological signatures observed along ruptured segment of the fault. In particular, geologists noted that the geological signatures were highly variable. Indeed, they were witnessing evidence that the two sides of a relatively linear segment of the fault had undergone transport in opposing directions extending over hundreds of kilometers. They recognized northward movement on the west side (now identified with the Pacific Plate) relative to southward movement on the east side (now identified with the North American Plate). The heterogeneous and nonuniform character of the different rock types – with different compositions, mineralogical content, and history – underscored how complicated and varied were the geochemical and geophysical signatures present.

An amazing outcome of this report was the development by one of its members, Professor Harry Fielding Reid of Johns Hopkins University, of the “elastic rebound theory.” He concluded that the crust of the Earth can gradually store elastic stress – due to what we now know is due to the underlying mantle motion driving the tectonic plates above – and that the earthquake must have involved an “elastic rebound” of

previously stored elastic stress. His conjecture was supported by numerous photographs showing fences that were literally sheared by the movement below of the segments of earth material to which they were attached. The resulting offset was approximately 2.5 m, although the relative displacement observed along the rupture was somewhat variable. Figure 4 illustrates this using an effective time sequence of one of those fences as seen from above and the evolution of the seismic event from (1) before the event, (2) during the event, and finally (3) after movement stopped. One memorable image shows two displaced segments of the fence with a “patch” constructed connecting the two decoupled segments.

A hint as to the complicated nature of failure is offered by the analogy that one can make with a long thin piece of wood being forcibly bent at each end in opposing directions to form an arc with steadily increasing curvature with the progress of time. Ultimately, we expect that it must break – but when it will and where along its length remains unpredictable. This metaphor illustrates a possible link to “critical point phenomena” and why earthquake prediction remains highly elusive.

An additional aspect of the elastic rebound conjecture is that we can obtain evidence identified via “paleoseismology” that establishes an existing pattern. Previous earthquakes indicate that recurrent events can occur showing a crude measure of periodicity, although the time window for a major event remains highly uncertain. Nevertheless, probabilistic approaches have been utilized to estimate approximately the maximum magnitude, return period, and geological fault slip for future events and produce a “probability” of an earthquake in a certain area during a specified window of time, as we mentioned previously with respect to southern California.

This narrative, given the highly fragmented nature of California faults displayed in Fig. 3, is a gross oversimplification of what we appreciate better today. The notion that a simple frictional model can be employed to describe the interaction between the two “faces” of a fault is oversimplified. Those faces are themselves the product of seemingly countless seismic events and are highly irregular and crenulated, thereby presenting an indescribably complicated picture of the fault geometry and how it varies along its length. Indeed, we expect fragments on many length scales to form between the rock faces, making the interaction of the rock faces even more complex. Thus, the San Andreas near the site of the 1857 Fort Tejon earthquake near present-day Palmdale has the two fault surfaces separated by 1–2 km with the intervening volume filled by the rock rubble and detritus of materials fractured earlier. This rubble is referred to as “fault gouge” and that volume as the “damage zone.” Interestingly, the rubble assembly will typically drop at various locations below the level of the two opposing rock faces, establishing locations where rainwater can accumulate and, thereby, form “sag ponds.”

Rock mechanics as it has come to be known, quite unlike fluid mechanics, is a very approximate phenomenological

Earthquake Complexity,

Earthquake Complexity, Fig. 4 Illustration of elastic rebound theory for the 1906 San Francisco earthquake developed by H.F. Reid (1911). (Adapted from <https://earthquake.usgs.gov/earthquakes/events/1906calif/18april/reid.php>)

theory. The added reality of heterogeneous rock types, fluidization, variable thermal histories, and so on makes it all the more clear that earthquake prediction is an unrealistic and unattainable goal. Modern continuum mechanics, which provides a mathematical first-principles but approximate basis for consideration, provides the equations underlying elastic wave as well as some insight into “plastic” and other dissipative “non-Newtonian” systems. However, those features are largely empirical and parameter based at best – see, for instance, Newman (2012) – thereby leaving open the question of where can we go from here.

We have already introduced the concepts attendant to pattern formation, namely, the isolation and identification for long-time large-area risk assessment. Data assimilation,

allowing for the regular updating of inputs to models for events, can provide a route to nowcasting amidst emergent developments in machine intelligence utilized over hours or, possibly, days. The 1906 San Francisco earthquake was preceded by a foreshock ≈ 25 seconds earlier – but only $\approx 30\%$ of seismic events are foreshocks – and it provided no hint as to the coming main shock, which lasted 42 seconds. In contrast, the 1964 Great Alaska Good Friday earthquake with a magnitude of 9.2 produced shaking over several minutes and a tsunami that ultimately destroyed the Chilean navy. Fortuitously, the risk presented by tsunamis can be established following a great earthquake taking place primarily in the Pacific, but the earthquake that produced it cannot be predicted. Hence, we remain limited by our inability to predict complex events such as earthquakes, among others. The take-home lesson here is that we can and, of necessity, must prepare for seismic events in earthquake-prone areas, particularly around the ring of fire whose human population continues to grow.

Burridge–Knopoff Model (1967) as a Paradigm for Complexity

Simple models may provide additional insight into the complex nature of earthquakes, and, possibly, some of these insights could yield clues into the kinds of nonlinear phenomena present. A useful summary of some of these models and the characteristic nonlinear phenomena that they can help elucidate may be found in the review by Shcherbakov et al. (2015). We will end our treatment of earthquake complexity by presenting one of the earliest yet simplest models for the elastic rebound theory and its possible link to the Gutenberg–Richter (power-law) frequency–magnitude relation. Figure 5 illustrates the Burridge and Knopoff (1967) or slider-block model. While often described as a model for deterministic chaos, demonstrating sensitivity to initial conditions, it can

Earthquake Complexity, Fig. 5 Depiction of the Burridge and Knopoff (1967) model, commonly called the slider-block model, for the elastic rebound theory. (Adapted from Newman (2012))

incorporate a very large number of constituent parts and, therefore, becomes a high-degree-of-freedom system and, in the continuum limit, an infinite-degree-of-freedom or complex system. Let us provide a simple description of how this toy model operates – a more complete description may be found in Newman (2012) and, especially, Burridge and Knopoff (1967).

Specifically, this model is designed to describe the “stick–slip” behavior associated with earthquake faults. We described earlier the highly complicated geomorphological nature of earthquake faults and the intervening damage zone and fault gouge; clearly, the Burridge–Knopoff model is a skeletal or toy depiction of that problematic reality. The model incorporates a solid, massive block with a rough surface, depicting one fault surface and an amalgam of identical weights or slider blocks connected by springs that satisfy Hooke’s linear force law for the other fault that is being driven by a weight shown on the right-hand side. The weight, then, may be regarded as the plate tectonic forces arising from mantle motion below the plates forcing the plates to move relative to each other subject to irregular resistive “frictional” forces. Each slider block is assumed to have its horizontal motion resisted by a frictional force proportional to its weight. In this scheme, the connecting springs apply dynamic forces to each of the blocks; however, a given block will resist moving unless the combination of the two springs acting upon it provides a force greater than that of friction. A given block will not move unless the spring forces apply exceed the force of static friction. Should that happen, the block will move in accord with Newton’s force law, thereby causing the connecting springs to respond and “slip,” resulting in a reduction of the net force that springs provide below the frictional limit, whereupon the affected block will once again “stick.” Suppose, now, that the system of slider blocks is at rest and allow the weight on the right-hand side (representing tectonic stresses) to increase. Ultimately one block will slip and, in the process of its altering the extension of the adjoining springs, could cause an adjacent block to slip; this process could repeat itself among other blocks... Every time a block slips, we identify an earthquake since this presents a metaphor for the Earth shaking at that spot. Most of the time, only isolated individual blocks will slip, but there will be times when 2 or 3 or ... will slip. It is appropriate to regard this as a kind of “chain reaction” that can be interpreted as a form of pattern formation and self-organization, offering further the

possibility of some form of critical point behavior. The magnitude of an earthquake corresponds to the number (or the logarithm of the number) of blocks that suddenly move. Meanwhile, the frequency of events is simply a number count of events of a given size, that is, the number count of blocks that respond. Remarkably, power-law statistics not unlike the Gutenberg–Richter law emerge, often associated with fractal behavior. An infinitesimal change in the original position of any of the slider blocks will result after a short period of time in an unrecognizably different configuration, yet one that preserves the overall power-law frequency–magnitude statistic. This model can readily be modified to allow for heterogeneity and, not surprisingly, the linear chain can be extended to form hierarchical networks. In other words, this deceptively simple model can show indications of many, if not all, of the features observed in real earthquakes. It is highly instructive to construct such a model numerically or build a physical “toy” using blocks connected by springs and so on as shown in Fig. 5. Despite its overall simplicity, we can readily identify its overarching complexity and emerge in the process with an appreciation that earthquake prediction remains an impossible dream. However, we can also come away from this experiment with a belief that, with adequate updating of our knowledge of the state of the Earth and the application of data assimilation from all possible precursors, some limited success may be achieved via nowcasting.

Summary and Conclusions

Natural hazards and earthquakes, especially, result in major losses of life and property. Ideally, we wish to develop methods for predicting earthquakes and, thereby, reduce human suffering and loss. It is important to note that inaccurate prediction schemes are profoundly problematic since they will fail to predict major events and will claim to “predict” events that do not take place – both of these situations have substantial and potentially tragic outcomes.

Some patterns emerge when considering seismic activity, particularly their proclivity to occur in specific regions of the globe on earthquake faults. This applies to seismicity with a limited degree of temporal regularity but with substantial variation in recurrence time. These features are evident from the historical record and what has come to be called the “paleoseismic” record, which incorporates natural indicators

of drastic change. For instance, the severed roots of trees that straddled a fault and their annular tree rings provide indications of when the earthquake took place and the magnitude of the lateral displacement displayed by their broken roots on the two sides of the fault. Of particular importance, the ring of fire, which figuratively encircles the Pacific Ocean, is especially geologically active owing to plate tectonic dynamics while at the same time is home to rapidly growing population centers – approximately 70% of earthquake activity takes place there.

The geological features and processes underlying earthquake faults are also remarkably complicated. Earthquake faults exhibit a remarkable degree of compositional heterogeneity as well as highly irregular geometries and variable stress distributions along their length. We employed the detailed investigation of the 1906 San Francisco earthquake to illustrate this point. The tendency among many mathematical geoscientists to treat earthquakes solely as “events” represents earthquakes as points in a space–time continuum according to their epicenter locations and rupture initiation times. While rupture may be initiated at a point, it will grow and could propagate over hundreds of kilometers extending over seconds to possibly minutes of time. Collectively, these factors make it very difficult, if not impossible, to develop mathematical models to describe the evolution of earthquake faults and their potential for failure. However, mathematical models such as the pioneering Burridge and Knopoff (1967) model provide our intuition with a simple yet deeper appreciation for what nature is displaying, and also serves as an example of a mathematical “complex” system.

Seismic activity is an illustration of mathematical complexity that is observed in other natural and social phenomena: these are associated with (a) dynamically active systems with very large numbers of degrees of freedom and having substantial sensitivity to initial conditions, (b) statistical or probabilistic scaling features sometimes referred to a “laws,” (c) fractal geometric structure associated with hierarchical networks and topologies, and (d) collectively may appear to undergo self-organization. Simply put, these aspects of seismicity have defeated efforts to develop prediction schemes with any modicum of reliability. Earthquakes are fundamentally complex phenomena.

There have emerged advances recently in machine learning and artificial intelligence methodologies that offer some hope. In other arenas displaying complexity, such as numerical weather prediction and the advent of “nowcasting,” these methodological advances have demonstrated a limited capacity to make forecasts. By coupling the progress made using these new computational technologies with the ability to assemble and analyze massive data sets with time-adaptive algorithms, there is emerging a possibility that we could obtain some limited success in anticipating major seismic events.

Unless such efforts prove reliable, we have no alternative but to pursue a three-pronged approach to earthquake hazard

mitigation: (a) develop and enforce earthquake-proof construction standards together, (b) engage everyone in maintaining safe living and work environments, and (c) prepare for the aftermath of such events when social and commercial disruption are to be expected. Further, we should utilize the velocity differences in the initial but less destructive P-waves and the inevitable and much more destructive S-waves. When employed in major earthquake-prone urban centers, time intervals of tens of seconds or more could provide the margin of safety needed to switch on alternative, independent power supplies, turn off potentially dangerous natural gas and other fire hazards, and provide individuals an opportunity to take cover or to find appropriate shelter. If all of these measures are rigorously pursued, then we will be able to “ride out” such events with relatively few casualties and limited property loss, which is a fundamental benefit for the study of all natural hazards.

Eigenvalues and Eigenvectors

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International Institute of Information Technology Bangalore, Electronic City, Bangalore, Karnataka, India

Definition

In linear algebra, a linear transformation refers to a mapping between two vector spaces that preserve operations of vector

addition and scalar multiplication, such that $\mathcal{L} : \mathcal{V} \rightarrow \mathcal{W}$, where $(\mathcal{V}, \mathbb{F})$ and $(\mathcal{W}, \mathbb{F})$ are vector spaces defined over a field $\mathbb{F}$. The commonly known linear transformations that can be expressed geometrically are rotation at a fixed point about an axis and scaling along the basis vectors. To understand rotation and scaling, they can be understood with respect to a three-dimensional (3D) object and the basis vectors, i.e., x , y , and z axes in the Cartesian coordinate space. In computer graphics, an object is often represented using a surface mesh, discretized into triangles. The vertices of the triangles in the mesh can be rotated or scaled to rotate or scale the object, respectively. These vertices can be written as 3D column vectors. So, what is the relationship between linear transformations and *eigenvalues and eigenvectors*? To explain the relationship, the representation theorem for the linear transformations must be discussed. The theorem states that a linear transformation $\mathcal{L} : \mathcal{V} \rightarrow \mathcal{W}$ can be represented as a matrix A , where the matrix is computed from the bases of $\mathcal{V}$ and $\mathcal{W}$. The matrix $A = \{a_{ij}\} \in \mathbb{R}^{m \times n}$ gives the transformed basis vector of $\mathcal{V}$ as $\mathcal{L}v_i = \sum_{k=1}^m a_{ki} w_k$. Thus, $A : \mathbb{R}^n \rightarrow \mathbb{R}^m$. When the dimensionality is the same for the domain and co-domain, A is a square matrix, i.e., $A \in \mathbb{R}^n \times \mathbb{R}^n$. Focusing on square matrices alone here, upon multiplying A with an arbitrary n -dimensional column vector $\mathbf{x}$, the matrix vector product $A\mathbf{x}$ is a transformation of x involving both rotation and scaling. However, there exist rotation-invariant vectors that can scale, which means the resultant vector $A\mathbf{x}$ is either a compressed or an elongated version of $\mathbf{x}$ itself, but with the same orientation as $\mathbf{x}$. Thus, such a vector $\mathbf{x}$ is a property of the matrix A . Thus, rewriting as $A\mathbf{x} = \lambda\mathbf{x}$, the vector $\mathbf{x}$ is referred to as the “right eigenvector of A ,” and λ is a scalar called as the “eigenvalue that corresponds to x ,” and $\lambda \in \mathbb{R}$. Similarly, for $y \in \mathbb{R}^n$, if $y^T A = \mu y^T$, for a scalar value μ , then y is referred to as the “left eigenvector of A ,” and μ is the eigenvalue that corresponds to y . Thus, the left eigenvector of A becomes the right eigenvector of its transpose, A^T , and vice versa.

Overview

The problem of finding the eigenvectors and corresponding eigenvalues of a square matrix is called eigenvalue decomposition of the matrix. It is also a way to factorize the matrix. The eigenvalue decomposition solves for an equation $A\mathbf{x} = \lambda\mathbf{x}$ (Heath 2018). Conventionally, the computational methods are designed to find the right eigenvectors, for which the set of eigenvalues is referred to as $\lambda(A) = \{\lambda\}$. The determinant of $(A - \lambda I_n)$ is referred to as the *characteristic polynomial* of A , p_A , where I_n is the identity matrix of size n . The solution to the equation is given by $(p_A = 0)$. Algebraic multiplicity of an eigenvalue λ of A is the number of times λ occurs as the root

of p_A . A similar property of eigenvalues is its geometric multiplicity, where it is the dimensionality of the eigenspace of A . Eigenspace ϵ_A is the nullspace $(A - \lambda I_n)$. The geometric multiplicity of an eigenvalue is also defined as the number of linearly independent eigenvectors that are associated with the eigenvalue. For every eigenvalue λ of A , the geometric multiplicity need not be the same as the algebraic multiplicity, but cannot exceed the algebraic multiplicity. A is diagonalizable when every eigenvalue has its geometric multiplicity equal to the algebraic one.

The equation is conventionally solved by transforming it to where the characteristic polynomial is zero and solving for the same. While this approach works for small values of n , for general cases, methods such as power iteration, inverse iteration, Rayleigh quotient iteration, simultaneous iteration, orthogonal iteration, and QR iteration are used. QR iteration is popularly used in this regard, where it is implemented as a two-stage process, involving the generation of tridiagonal and diagonal matrices. The eigenvalue problems in practice tend to take the form $A\mathbf{x} = \lambda B\mathbf{x}$, which is also referred to as the generalized eigenvalue problem. If A and B are both non-singular, then the generalized eigenvalue problem can be reduced to the standard format, as $(B^{-1}A)\mathbf{x} = \lambda\mathbf{x}$ or $(A^{-1}B)\mathbf{x} = (1/\lambda)\mathbf{x}$.

Compared to these iterative methods of finding all eigenvectors and eigenvalues, which are of $O(n^3)$ complexity, an alternative, efficient strategy is to find eigenvalues using an $O(n^2)$ algorithm and then using inverse iteration for computing the corresponding eigenvectors. This is the strategy used in the relatively robust representation (RRR) method. This method can also be adapted to determining selected eigenvalues instead of exhaustively finding all eigenvalues to make the algorithms more efficient and fulfilling the exact requirements of the eigenvalues. Additionally, in order to improve the numerical accuracy of the computed eigenvalues and eigenvectors, numerically stable libraries in EISPACK, LAPACK, etc., with extended precision arithmetic are used.

Eigenvalue decomposition is related to singular value decomposition (SVD) as the singular values of a rectangular matrix, say, C of size $m \times n$, are the non-negative square roots of the eigenvalues of $A^T A$. SVD gives $C = U\Sigma V$, where U and V are orthogonal matrices of sizes m and n , respectively. It is also known that the columns of U and V are orthonormal eigenvalues of AA^T and $A^T A$, respectively.

It is important to know that eigenvalue decomposition has a close connection with the *spectral theory*. The set $\lambda(A)$ is also referred to as the spectrum of A . The maximum absolute value of the eigenvalues is called spectral radius of A , $\rho(A) = \max \{|\lambda| : \lambda \in \lambda(A)\}$. If A is symmetric and diagonalizable, then the decomposition gives $A = Q\Lambda Q^T$, where Q is an orthogonal matrix with eigenvectors as rows, and Λ is a diagonal matrix with eigenvalues, in the same order as the eigenvectors are positioned in Q . This decomposition, thus,

provides the quadratic form of $\mathbf{A}$. If the eigenvalues are unique, then $\mathbf{Q}$, $\mathbf{\Lambda}$, and $\mathbf{A}$ are matrices of the same size. The introductory content so far discussed in this chapter has been summarized from the textbooks by Laub (2004) and Heath (2018).

Hawkins (1975) has documented the history of eigenvalue problems in the eighteenth century, including the key contributions by Cauchy, d'Alembert, Lagrange, and Laplace. The connections between spectral theory and eigenvalues stem from astronomical applications (Hawkins 1975). The history includes the principal axes theorem that uses eigenvalue decomposition for reduction to the normal form of a symmetric bilinear form and the diagonalization of a real symmetric matrix (Steen 1973). Hilbert had then extended the principal axes theorem by generalizing the concept of eigenvalue through the definition of the spectrum of symmetric matrices. The subset of $\lambda(\mathbf{A})$ for which the equation $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ has trivial solutions is referred to as the point spectrum of $\mathbf{A}$, and its complement is called the continuous spectrum. During 1904–1907, Hilbert–Schmidt spectral theory was developed, which explores the use of linear transformations in infinite-dimensional space by using the quadratic forms obtained during eigenvalue decomposition (Steen 1973). Since then, there have been several successors of the Hilbert–Schmidt spectral theory.

Applications with Focus on Covariance Matrix

Principal component analysis (PCA) is a dimensionality reduction algorithm that traces back its history to Karl Pearson and Hotelling. This involves identifying a new orthogonal space to describe a set of n -dimensional points, in such a way that the axes are ordered by decreasing levels of variance along the axis. These new dimensions are called *principal components*. The use of PCA in spatial data involves two approaches (Demšar et al. 2013), where in the first approach PCA is applied to nonspatial attribute data, and in the second approach, it is applied directly to the geographic data. PCA leads to factorization of a rectangular matrix of m measurements and n variables, $\mathbf{X}$, given by $\mathbf{X} = \mathbf{TP}^T$, where $\mathbf{T}$ is the projection of $\mathbf{X}$ onto an r -dimensional space, $\mathbf{P}$, $\mathbf{P}$ is an orthonormal projection matrix, and r is the matrix rank of $\mathbf{X}$. The score matrix $\mathbf{T} \in \mathbb{R}^n \times r$, and the loading matrix $\mathbf{P} \in \mathbb{R}^m \times r$. Dimensionality reduction occurs when only considering dimensions with significant eigenvalue, thus, truncating the eigenvalue set and modifying the original matrix $\mathbf{X}$ to $\mathbf{X}' \in \mathbb{R}^m \times r$. The principal components correspond to eigenvectors of the covariance or correlation matrix $\mathbf{\Sigma}$, given as $\mathbf{\Sigma} = \frac{\mathbf{X}'^T \mathbf{X}}{m-1} = \mathbf{P}\mathbf{\Lambda}\mathbf{P}^T$.

In the case of spatial data, PCA gives the shape of local neighborhood, which is used in point cloud analysis for light

detection and ranging (LiDAR) (Jutzi and Gross 2009). The shape of the local neighborhood is quantified using a local geometric descriptor, computed as the covariance matrix $\mathbf{\Sigma}$ of position coordinates of the point with respect to its selected local neighbors. $\mathbf{\Sigma}$ of each point provides its geometric features, which are further used in supervised learning classifier for semantic classification.

In geospatial data, PCA is widely used on image or raster data. PCA can be applied to satellite images with N pixels and b bands to compute the covariance matrix $\mathbf{\Sigma} \in \mathbb{R}^{b \times b}$. The significant principal components are computed using eigenvalue decomposition of $\mathbf{\Sigma}$. For change detection in land-use cover owing to forest fires (Estornell et al. 2013), the eigenvalues of the second principal component helped in identifying the perimeter of the region affected by the forest fires. Similarly, for synthetic aperture radar (SAR) images, the covariance matrix is used for PCA, where the first and second eigenvalue maps of the pixels give the dominant and secondary backscattering mechanism selection (Fornaro et al. 2014). In polarimetric SAR (Pol-SAR) images, the eigenvalue decomposition of the polarimetric covariance matrices (PCMs) gives the segmentation of areas, classification of typology, and identification of scattering mechanisms (Addabbo et al. 2019).

Summary

Overall, eigenvalue decomposition of linear transformations or measurement matrices has been a powerful tool for information extraction from spatial as well as nonspatial data in geoscientific applications.

Electrofacies

John H. Doveton
Kansas Geological Survey, University of Kansas, Lawrence,
KS, USA

Definition

The term electrofacies was first introduced and defined to be “the set of log responses which characterizes a bed and permits it to be distinguished from the other” (Serra and Abbott 1980).

Facies and Electrofacies

A widely quoted definition of facies is “A facies should ideally be a distinctive rock that forms under certain conditions of sedimentation reflecting a particular process or environment” (Reading 1978). In contrast, an electrofacies is a collective association of log responses that are linked with geological attributes either implicitly through interpretation or explicitly linked to a lithology database. Electrofacies are clearly determined by geology, because log responses are measurements of the physical properties of rocks. The intent of electrofacies identification is generally to match them with lithofacies identified in the core or an outcrop.

An important philosophical distinction between electrofacies and “classical” geological facies is that electrofacies are primarily observational in origin, and facies are traditionally rooted in genesis. Electrofacies can be distinctive empirical log-response associations, but whether they reflect

depositional environment, diagenetic over-prints, or other processes requires careful consideration on a case-by-case basis.

Supervised and Unsupervised Models

An electrofacies analysis that is given no prior information concerning group membership of individual observations is an “unsupervised” approach, where trends and clusters that are perceived in petrophysical measurements are subsequently assigned geological meaning. This inductive philosophy “allows the data to speak for themselves” and operates from the “bottom-up,” because the analysis originates with the observational data rather than being driven top-down by a deductive model. Advantages include the element of surprise, in that new associations may be revealed that represent useful information to augment the current geological model (Delfiner et al. 1987). An example is shown in Fig. 1, where a crossplot of the first two principal components of a petrophysical log suite (right) is used to identify electrofacies, which then are assigned to a Permian carbonate/clastic sequence (left). A comparison between this electrofacies succession and facies observed from core is shown in Fig. 2.

In a “supervised” method, different categories or groups are specified before the analysis; the goal of the method is to find the best function to distinguish the categories, based on the characteristics of the data. Subsequently, the function can be used to classify unknown observations on the basis of likelihood of membership in one or another of the groups. In this case, lithofacies are identified in the core and linked with log data from a cored well as a “training set,” from which a multivariate statistical method can “learn” the relationships between logs and core lithofacies. The matching of predicted lithofacies with modern depositional analogs means that dimensional measures, such as shape and lateral extent, can be used to correlate genetic layers across a field in a satisfactory geomodel. Most wells are logged rather than cored, so that lithofacies predicted from electrofacies are important in augmenting sparsely distributed cored wells.

Parametric Methods

A simple model of an electrofacies can be approximated by a cloud of points that are concentrated in the center and diffuse in density outward. A multivariate normal distribution provides a convenient means to model such a distribution efficiently. It also provides the basis for a probability model that

Electrofacies, Fig. 1 Crossplot of the first two principal components of a petrophysical log suite (right) from a Permian carbonate/clastic section is used to identify electrofacies, which then are assigned to a stratigraphic sequence (left)

allows statistical classifications to be made from a database of multiple electrofacies. If approximately normal, then each electrofacies data cloud is a hyperellipsoid that can be specified completely by the statistics of the multivariate mean and the matrix of variances and covariances between the logs.

Although the locations of data points in multilog space collectively delineate clouds with the same number of dimensions as logs, they can often be mapped effectively in a much reduced dimensionality. This is because intercorrelations between the log variables cause the clouds to be extended along certain trends. Principal component analysis computes an ordered set of orthogonal axes that absorb the variation in a systematic manner (Wolff and Pelissier-Combescur 1982). Clustering is then run in two phases. In the first phase, the clustering is used to isolate local modes as zonal representatives of the digital data. In the second phase, the local modes are agglomerated into clusters that are equated with electrofacies. Decisions concerning potential cluster subdivision or fusion are monitored by referral to geological information from the core or from geological experience.

Alternatively, multiple discriminant analysis can be used to classify electrofacies that are keyed to a lithofacies database, first for classification and then for prediction (Doveton 1994).

Nonparametric and Neural Network Methods

The representation of electrofacies data clouds by multinormal hyperellipsoids is a simple model that is often a poorly adequate representation of real data variation. The richly connected structure of neural networks allows a more nuanced treatment of multiple log data (Doveton 2014). However, careful evaluations must be made of predictive results to ensure that the network is not overfitting the data. This is achieved by linking neural network training with validation data sets. The methodology is particularly appropriate when constructing large geomodels based on a well set that has been extensively logged, but with limited core data (Dubois et al. 2006).

Electrofacies, Fig. 2 A comparison between the unsupervised electrofacies succession and the facies observed from core examination

Summary

Electrofacies are clusters of multiple log responses that distinguish rock types in the subsurface. Their geological meaning can be interpreted by pattern recognition, but they more commonly are linked explicitly with lithofacies observed in core or from drill-cuttings. Electrofacies analysis is particularly important in the construction of geomodels, because core information is typically much less available than petrophysical logs in the majority of wells. Consequently, observations from core can be used to train logs in uncored wells in the prediction of lithofacies.

Ensemble Kalman Filtering

J. Jaime Gómez-Hernández

Research Institute of Water and Environmental Engineering,
Universitat Politècnica de València, Valencia, Spain

Definition

The ensemble Kalman filter (EnKF) is an evolution of the Kalman filter for its application to nonlinear state-transition systems with a further extension to serve as a powerful parameter inversion method. Its main purpose is to improve the estimates of the system state as observations are acquired. As the Kalman filter, the EnKF is based on two steps, forecasting and updating (or filtering). During the forecasting step, the state of the system is forecasted on the basis of the latest state estimate; then, forecasts are compared with observations and a correction is made to the state (and possibly to the parameters of the state equation) that will serve as the basis for the next forecast.

The Kalman filter was developed by Kalman (1960) for the purpose of improving the trajectory estimation of spacecrafts and missiles and one of its very first implementations was in the Apollo program. The Kalman filter, as developed by Kalman, had a great success when it was first proposed since it provides optimal results for dynamic systems that are controlled by a linear state-transition equation; then, it went into oblivion because it did not work so well when dealing with nonlinear systems. New formulations such as the extended Kalman filter were postulated with limited success, but it was not until the work by Evensen (1994), who introduced the EnKF as a mean to deal with the nonlinearities, that the Kalman filter came back into the spotlight. This rebirth of the Kalman filter not only allowed a better modeling of nonlinear systems but also proved that it can be used as a very efficient inverse modeling approach for the identification of parameters of the state-transition equations.

The Kalman Filter

Consider a dynamic system evolving in time according to a state-transition equation. There are two ways to predict the

state system at time t : (i) by dead reckoning, that is, the state-transition model is run until time t given some known state at time 0, or (ii) by observing the state of the system using measuring probes. Neither way will provide an exact description of the state of the system at time t , the first one, because the state-transition model is always an approximation of the real system, and the second one, because the probes always have measurement errors and, generally, only sample sparsely the state itself. Kalman found a way to combine the two predictions into a better one in his formulation of his filter.

Kalman formulated his filter for a linear dynamic system

$$x^t = \mathcal{L}(x^{t-1}) \quad (1)$$

where x is the state of the system, and $\mathcal{L}$ the linear state-transition equation that gives the state of the system at time t given its state in a previous instant $t - 1$. Since most of the models used in the geosciences are built on discretized versions of the real system, a matrix notation can be used to describe the evolution of the system

$$\mathbf{x}^t = \mathbf{A} \cdot \mathbf{x}^{t-1} \quad (2)$$

where $\mathbf{x}$ is a column vector of size $N \times 1$ with the values of the state at the centers of the N voxels that discretize the study area, and $\mathbf{A}$ is a state-transition matrix of size $N \times N$.

Adopting a random function model, we can interpret each element of $\mathbf{x}$, at any time t , as a random variable, and the entire vector, at any time t , as a random function. As a consequence, the expected value of the random function propagates in time according to

$$E \{ \mathbf{x}^t \} = \mathbf{A} \cdot E \{ \mathbf{x}^{t-1} \}, \quad (3)$$

and its covariance, according to

$$C(\mathbf{x}^t) = \mathbf{A} \cdot C(\mathbf{x}^{t-1}) \cdot \mathbf{A}', \quad (4)$$

where C is a covariance matrix of size $N \times N$ containing all pairwise covariances between any two elements in the vector state and the $'$ symbol is used to denote transpose.

Now, consider that the state has been observed at M locations (generally $M \ll N$). These observations are represented by vector $\mathbf{y}$. For the sake of simplicity, assume that these observations have been taken at the centers of the voxels that discretize the study area and that measure directly the state of the system not a proxy. This simplification implies that the observation matrix $\mathbf{H}$ that will be used later should be made up of just zeroes and ones and it serves to extract the specific rows and columns from the vectors and matrices used in the formulation that follows corresponding to the observation locations. Consider also that these observations have un-

correlated measurement errors with zero mean; the error covariance $\mathbf{R}$ is, therefore, diagonal. Under these considerations, the conditional expectation of the state at time t given the observations taken at that same time is the optimal estimate in a least-square sense of the state of the system and is given by the following expression:

$$E\{\mathbf{x}^t|\mathbf{y}^t\} = E\{\mathbf{x}^t\} + \mathbf{K} \cdot (\mathbf{y}^t - \mathbf{H} \cdot E\{\mathbf{x}^t\}) \quad (5)$$

where $\mathbf{K}$ is the so-called Kalman gain matrix of size $N \times M$, the expression of which is

$$\mathbf{K} = C(\mathbf{x}^t) \cdot \mathbf{H}' \cdot (\mathbf{H} \cdot C(\mathbf{x}^t) \cdot \mathbf{H}' + \mathbf{R}^t)^{-1}. \quad (6)$$

The analysis of expression (5) shows that the conditional expectation is equal to the unconditional one corrected by a factor that is proportional to the discrepancy between the observations and the predicted expected data at time t obtained with Eq. (3). The proportionality term is itself proportional to the predicted state covariance at time t , and inverse proportional to the measurement error covariance and to the covariance between the locations at which the state has been observed.

The conditional covariance is given by

$$C(\mathbf{x}^t|\mathbf{y}^t) = (\mathbf{I} - \mathbf{K} \cdot \mathbf{H}) \cdot C(\mathbf{x}^t); \quad (7)$$

it is the covariance associated with the conditional expectation.

The Kalman filter consists of two steps. A forecast step, given by Eq. (3) and an update step given by Eq. (5). Alongside, the covariances are also forecasted and updated (Eqs. (4) and (7), respectively). The predictions are based on the linear state transition equation and the updates are the result of an optimization in some least squares sense. Once the updates are made, they become the basis for the next forecast and update from t to $t + 1$.

As described, the method is straightforward to implement and apply. One of its first applications was to help the guidance of the Apollo spacecrafts and it was coded in the Apollo computer, a computer with only 2 kilobytes of RAM, 36 kilobytes of ROM, and a chip running at 100 MHz.

The Extended Kalman Filter

Given its success with linear dynamic systems, an attempt to expand the Kalman filter to deal with nonlinear state transition equations was done with the Extended Kalman filter (Jazwinski 1970). When the system does not evolve linearly

$$\mathbf{x}^t = \Phi(\mathbf{x}^{t-1}) \quad (8)$$

with Φ being a nonlinear operator, a Taylor expansion can be applied to get a linear approximation

$$\mathbf{x}^t \approx \mathbf{A} \cdot \mathbf{x}^{t-1} + \dots \quad (9)$$

and

$$C(\mathbf{x}^t) \approx \mathbf{A} \cdot C(\mathbf{x}^{t-1}) \cdot \mathbf{A}' + \dots, \quad (10)$$

with

$$\mathbf{A} = \frac{\partial \Phi}{\partial \mathbf{x}^t} \quad (11)$$

being the Jacobian of the state transition equation. When only the first term of the expansion is retained, the formulation defaults to the Kalman filter formulation, which is then applied. The main problem with this approach is that, even if the Jacobian is reevaluated after each update step, the covariance estimate deteriorates quickly in time when Eq. (10) is used, yielding very poor results.

The Ensemble Kalman Filter

An improved method to compute the state covariances for nonlinear systems was proposed by Evensen (1994) circumventing the main problem of the extended Kalman filter. A random function can be defined by the statistics of the random variables that conform it, or as a collection of realizations. Evensen replaced working directly with the expected value and covariance of the random function by working with an ensemble of realizations, which are forecasted and updated as per Kalman filter theory. Then, he proposes to compute, experimentally, the expected value and covariance from the forecasted realizations. There is no need to approximate the forecast of neither the mean nor the covariance as in Eqs. (9) and (10); rather, the ensemble of realizations are forecasted in time using the nonlinear transfer function of Eq. (8) and the expected values and covariances are computed afterwards from the set of forecasted realizations.

Consider an ensemble of K realizations from the random function $\mathbf{x}$, at time $t - 1$, $\{\mathbf{x}_1^{t-1}, \mathbf{x}_2^{t-1}, \dots, \mathbf{x}_K^{t-1}\}$, each realization composed of N components corresponding to the N state values associated to the discretization of the study area. They propagate in time according to the nonlinear transfer function Φ

$$\{\mathbf{x}_1^t, \mathbf{x}_2^t, \dots, \mathbf{x}_K^t\} = \Phi\{\mathbf{x}_1^{t-1}, \mathbf{x}_2^{t-1}, \dots, \mathbf{x}_K^{t-1}\}. \quad (12)$$

The expected value and the covariance of the state random function can be approximated from this ensemble of forecasted realizations. Let $\mathbf{X}$ be an array with N rows and K columns containing all states for all realizations. The expected value is given by

$$E\{\mathbf{x}^t\} \approx \frac{1}{K} (\mathbf{X}^t \cdot \mathbf{1}_{K \times 1}) \quad (13)$$

where $\mathbf{1}_{K \times 1}$ is a column vector of K ones, and $\mathbf{X}^t$ contains all the forecasted realizations at time t . Likewise, the covariance is computed as

$$C(\mathbf{x}^t) \approx \frac{1}{K-1} (\mathbf{X}^t - E\{\mathbf{x}^t\} \cdot \mathbf{1}_{1 \times N}) \cdot (\mathbf{X}^t - E\{\mathbf{x}^t\} \cdot \mathbf{1}_{1 \times N})' \quad (14)$$

where $\mathbf{1}_{1 \times N}$ is a row vector of N ones. The Kalman gain is computed using Eq. (6) and all realizations are updated according to

$$\mathbf{X}^t | \mathbf{y}^t = \mathbf{X}^t + \mathbf{K} \cdot ((\mathbf{y}^t + \boldsymbol{\epsilon}^t) \cdot \mathbf{1}_{1 \times K} - \mathbf{H} \cdot \mathbf{X}^t) \quad (15)$$

where $\boldsymbol{\epsilon}^t$ is a vector of random observation errors drawn from the diagonal covariance matrix $\mathbf{R}$. The conditional expectation and the conditional co-variance could be computed, if needed, using $\mathbf{X}^t | \mathbf{y}^t$ in Eqs. (13) and (14) in replacement of $\mathbf{X}^t$. The conditional expectation would be the best estimate, in some least squares sense, of the state of the system at time t , and the conditional covariance a measure of the estimation uncertainty.

The ensemble of updated realizations becomes the new starting ensemble of realizations and the forecast and update steps are repeated starting at Eq. (12).

The algorithm for the ensemble Kalman filter is quite simple and applicable to any dynamic system; its steps would be to:

1. Generate an ensemble of realizations of the system state (these realizations can be generated by randomizing the parameters of the state equation and solving it, or by perturbing with noise a given solution of the state equation)
2. Forecast the state, realization by realization, until the next observation time (Eq. (8))
3. Compute the expected value and covariance of the forecasted realizations (Eqs. (9) and (10))
4. Compute the Kalman gain (Eq. (6))
5. Update the forecasted realizations (Eq. (15))
6. Compute the expected value and covariance of the updated realizations, if necessary (Eqs. (9) and (10))

7. Make the updated realizations the new starting realizations and return to the forecast step (Eq. (8))

The Ensemble Kalman Filter with Augmented State

The EnKF as proposed by Evensen solved the problem of the approximate calculation of the covariance matrices using an alternative (and better) approximation based on the statistical analysis of an ensemble of realizations, but its application had the same purpose as the original filter: the update of the system state each time new observations were obtained. But, it was realized that the method could be used to update the parameters defining the system, too. In modeling, for instance, an aquifer, these parameters could be material parameters such as permeability or porosity, forcing terms such as recharge or contaminant source locations, or boundary conditions such as lateral inflows/outflows or leakages. The idea consists of considering the parameters as part of an augmented state vector (Wen and Chen 2007), in which the parameters are updated each time a new observation is made.

The system state x is now augmented to include the last update of the model parameters α . The system state continues evolving in time according to a state-transition model Φ , but the model parameters do not evolve.

Forecast Eq. (3) becomes

$$\begin{Bmatrix} \alpha^t \\ x^t \end{Bmatrix} = \begin{Bmatrix} \alpha^{t-1} \\ \Phi(x^{t-1}) \end{Bmatrix} \quad (16)$$

Using z to represent the augmented state, a new forecast equation is defined

$$z^t = \Psi(z^{t-1}), \quad (17)$$

and the EnKF algorithm can be applied once a random function model is adopted for z . Each ensemble realization will contain a realization of the parameters and of the states associated to that parameter realization. The forecast will be performed using Eq. (17) on each realization, and the rest of the steps will follow the algorithm described in the previous section. Notice that new parameter observations can be included at the same time as new state observations.

This application of the EnKF becomes a powerful inverse modeling approach since, as observations are assimilated, improved estimates of the model parameters are obtained. The main criticism of this approach is the potential lack of consistency between the updated parameters and the updated state values. After all, the states should abide the principles under which the state-transition model is built, for instance, in the case of an aquifer modeling, the preservation of mass.

This possible inconsistency resulted in the proposal of a variant of the filter, the restart EnKF (Xu and Gómez-Hernández 2018), in which the system forecast is always made from time 0, rather than from the last updated estimate of the system state:

$$\begin{Bmatrix} \alpha^t \\ x^t \end{Bmatrix} = \begin{Bmatrix} \alpha^{t-1} \\ \Phi(x^0) \end{Bmatrix}. \quad (18)$$

The parameters keep being updated after each observation event, but the states are always recalculated from the state at time 0, x^0 , with the latest update of the parameters. This procedure obviously increases the running time of the algorithm but ensures that the state values are always consistent with the latest estimate of the model parameters.

The Normal-Score Ensemble Kalman Filter

There was still a pitfall in the application of the EnKF to nonlinear systems. The fact that all updates are made using covariances imbue a Gaussian flavor to the updated realizations, which, after several updates, have clear Gaussian attributes, starting by their histogram. In geosciences, many of the attributes have non-Gaussian characteristics, like, for instance, the permeabilities of a sand-shale aquifer have a histogram closer to a mixture of two lognormal distributions than to a Gaussian one. Even if the starting parameter realizations display the desired non-Gaussian characteristics, such as a bi-modality of the histograms, the final histograms of the parameter realizations get close to normal. To avoid this problem, the normal-score EnKF (NS-EnKF) was proposed by Zhou et al. (2011).

In the NS-EnKF, all the EnKF steps are performed in variables that are marginally Gaussian. The augmented state vector z is transformed into another one with marginal Gaussian distributions using a normal-score transform $\varphi(\cdot)$, which is a monotonic transformation that will yield a resulting variable with a standardized Gaussian histogram, then, given the normal-score transforms u^t and u^{t-1} of the augmented states z^t and z^{t-1}

$$u^{t-1} = \varphi^{t-1}(z^{t-1})$$

$$u^t = \varphi^t(z^t)$$

and given the state transition Eq. (17), a new forecast equation can be written for the normal-score variates

$$u^t = \Gamma(u^{t-1}), \quad (19)$$

with

$$\Gamma = \varphi^t \cdot \Psi \cdot (\varphi^{t-1})^{-1}. \quad (20)$$

The NS-EnKF proceeds as the EnKF but in normal-score space. At any time, the augmented state values z can be obtained by using the inverse of the normal-score transform $\varphi^{-1}(\cdot)$.

Kalman Filter and Kriging

The observant reader will find striking similarities between the update Eq. (5) and the simple kriging equation, with the Kalman gain being the kriging weights.

Summary and Conclusions

The ensemble Kalman filter is a variant of the Kalman filter capable to deal with dynamic nonlinear systems. It provides optimal estimates of the state of the system as well as of the parameters defining the state- transition model, which are updated sequentially in time as new observations are acquired. The rationale is simple as is its implementation, and could be used with virtually any model that allows predicting the state of the system in the future as a function of the state in the present. Its version using an augmented state vector has proven a very powerful and efficient inverse modeling approach.

Entropy

Julian M. Ortiz¹ and Jorge F. Silva²

¹The Robert M. Buchan Department of Mining, Queen's University, Kingston, ON, Canada

²Information and Decision System Group (IDS), Department of Electrical Engineering, University of Chile, Santiago, Chile

Definition

The *Shannon entropy* is a fundamental measure in information theory (Cover and Thomas 2006). Claude Shannon introduced it in his landmark 1948 paper (Shannon 1948), to quantify the level of randomness or statistical disorder that can be used to determine (encode) a discrete random object. In its basic form, we have a discrete random variable Z with values in a finite alphabet $\mathcal{A} = \{1, \dots, M\}$ equipped with a *probability mass function* (pmf) denoted by $P_Z = (p_Z(i))_{i \in \mathcal{A}}$. Then, the entropy of Z (or the entropy of its distribution P_Z) is given by:

$$\mathcal{H}(Z) = \mathcal{H}(P_Z) \equiv - \sum_{i=1}^M p_Z(i) \log p_Z(i). \quad (1)$$

The term $\log 1/p_Z(i)$ in (Eq. 1) is known as *the self-information* of the event $\{Z = i\}$ (Cover and Thomas 2006), and it can be understood as the level of surprise or information we obtain when Z takes the value i in the execution of this random experiment. The smaller the probability (before the execution of the experiment) of observing $\{Z = i\}$, the bigger the information we gain when measuring this outcome. Consequently, $\mathcal{H}(Z)$ is the average self-information or the information we obtain from observing Z on average. Indeed, when Z is deterministic ($p_Z(i) = 1$ for some $i \in \mathcal{A}$), then $\mathcal{H}(Z) = 0$, and $\mathcal{H}(Z)$ achieves its maximum value $\log M$ if, and only if, P_Z is the uniform distribution in $\mathcal{A}$ (Cover and Thomas 2006).

In communication, the log is based 2, and the *second Shannon coding theorem* (Cover and Thomas 2006; Shannon

1948) shows that $\mathcal{H}(Z)$ determines the minimum number of bits per sample needed to compress Z . Therefore, $\mathcal{H}(Z)$ is not an abstract (inapplicable) concept in digital communication: Shannon shows that $\mathcal{H}(Z)$ precisely indicates how costly (in bits) is the task of compressing Z .

In geosciences, we are interested in random objects with a spatial structure and specific local statistical features. Entropy has been used to measure the complexity or uncertainty of the local features and as a metric of overall spatial complexity (Wellmann and Regenauer-Lieb 2012; Journel and Deutsch 1993). Another interesting application of entropy is in the design of sampling networks and experimental design, intending to define the optimum sampling locations to reduce the overall uncertainty in a random field (Santibañez et al. 2019; Wellmann and Regenauer-Lieb 2012).

Historical Development and Properties

Historical Development

The entropy is one of the most important quantities in information theory introduced by Shannon to characterize the fundamental performance limit for the task of (fixed-rate) almost lossless data compression (Shannon 1948). The entropy has found numerous applications in other problems and fields far beyond its original conception in data compression and communication. For instance, it has been considered in the simulation problem, for experimental design, for the optimal sampling problem, and as a principle for learning, to name some examples.

Basic Properties of $\mathcal{H}(Z)$

The entropy of Z is an indicator of the disorder or uncertainty of Z , and it satisfies the following important properties:

- $\mathcal{H}(Z) = 0$ if, and only if, Z is deterministic¹.
- $\mathcal{H}(Z) \leq \log M$ and $\mathcal{H}(Z) = \log M$ if, and only if, Z has the uniform distribution over $[M] \equiv \{1, \dots, M\}$.
- If we have two probabilities μ and ν on $[M]$ and $w \in (0, 1)$:

$$\mathcal{H}(\underbrace{w\mu + (1-w)\nu}_{\text{convex combination}}) \geq w \cdot \mathcal{H}(\mu) + (1-w)\mathcal{H}(\nu), \quad (2)$$

then the entropy is a concave functional of the probabilities.

Conditional Entropy and Mutual Information

Information can be conceptualized as the reduction of uncertainty of an object after measuring a random experiment

¹This means that $p_Z(i) = 1$ for some $i \in [M]$.

Entropy, Fig. 1 Location map of the samples in the domain, coded with the corresponding category code

(Cover and Thomas 2006). Therefore, if we observe (measure) Z , we gain $\mathcal{H}(Z)$ of information about Z , in average. The reason is that before measuring Z , we have $\mathcal{H}(Z)$ of prior uncertainty (about Z). After measuring it, we do not have uncertainty as we ultimately resolved Z . Therefore, measuring Z provides in average $\mathcal{H}(Z)$ information.

If we have two discrete random variables (Z_1, Z_2) with joint distribution P_{Z_1, Z_2} over the space $[M] \times [N]$, we can ask a similar question: how much information in average Z_2 offers about Z_1 . This question is fully determined by the statistical interaction between Z_1 and Z_2 expressed by their joint probability. Following the same rationale, the prior uncertainty of Z_1 is $\mathcal{H}(Z_1)$ and the posterior uncertainty of Z_1 after observing Z_2 in average is given (denoted) by the *conditional entropy*:

$$\mathcal{H}(Z_1|Z_2) \equiv \sum_{z_2 \in [N]} P_{Z_2}(z_2) \cdot \mathcal{H}(P_{Z_1|Z_2}(|z_2)) \quad (3)$$

where $P_{Z_1|Z_2}(|z_2)$ denotes the conditional distribution of Z_1 given the event $\{Z_2 = z_2\}$. Consequently from (Eq. 1), $\mathcal{H}(P_{Z_1|Z_2}(|z_2))$ is the entropy of Z_1 given that $Z_2 = z_2$, and $\mathcal{H}(Z_2|Z_1)$ in (Eq. 3) is the average of those conditional entropies with respect to P_{Z_2} . Therefore, the information we gain about Z_1 from observing (measuring) Z_2 in average is:

$$I(Z_1; Z_2) \equiv \mathcal{H}(Z_1) - \mathcal{H}(Z_1|Z_2), \quad (4)$$

which is known as the *mutual information* (MI) between Z_1 and Z_2 . Important properties of $I(Z_1; Z_2)$ are (Cover and Thomas 2006):

- $\mathcal{H}(Z_1|Z_2) \leq \mathcal{H}(Z_1)$ and, consequently, $I(Z_1; Z_2) \geq 0$.
- $\mathcal{H}(Z_1) - \mathcal{H}(Z_1|Z_2) = \mathcal{H}(Z_2) - \mathcal{H}(Z_2|Z_1) = I(Z_1; Z_2)$.

- $I(Z_1; Z_2) = 0$ if, and only if, Z_1 and Z_2 are independent.
- $\mathcal{H}(Z_1|Z_2) = 0$ if, and only if, Z_1 is a deterministic function of Z_2 .
- $I(Z_1; Z_1) = \mathcal{H}(Z_1)$.

Interestingly, the amount of information we gain about Z_1 by observing (measuring) Z_2 is the same as the amount of information we gain about Z_2 by observing (measuring) Z_1 .

Another worth mentioning characterization of $I(Z_1; Z_2)$ comes from the divergence (or Kullback-Leibler divergence). The divergence between two distributions μ and ν in a finite alphabet space $[M]$ is given by (Cover and Thomas 2006):

$$D(\mu||\nu) = \sum_{i \in [M]} \mu(i) \log \frac{\mu(i)}{\nu(i)} \geq 0 \quad (5)$$

if $\mu \ll \nu$ ² and otherwise $D(\mu||\nu) = \infty$. Interestingly, using (Eq. 4) it is possible to show that:

$$I(Z_1; Z_2) = D(P_{Z_1, Z_2} || P_{Z_1} \times P_{Z_2}) \quad (6)$$

where $P_{Z_1} \times P_{Z_2}$ denotes the product distribution (i.e., $P_{Z_1} \times P_{Z_2}(i, j) = P_{Z_1}(i) \cdot P_{Z_2}(j)$).

Differential Entropy and Multivariate Case

This basic definition in (Eq. 1) can be extended to the case of continuous variables (Renyi 1959) and to the

²If $\nu(A) = 0$ then $\mu(A) = 0$.

multivariate case (Cover and Thomas 2006), which can be used to characterize the bivariate spatial variability of a random field (Journel and Deutsch 1993). For the univariate continuous variable Z equipped with a probability density function (pdf) f_Z , Eq. 1 can be extended as (Cover and Thomas 2006):

$$\begin{aligned} h(Z) &= h(f_Z) \equiv E\{-\log f_Z(z)\} \\ &= -\int_{-\infty}^{+\infty} [\log f_Z(z)] f_Z(z) dz, \end{aligned} \quad (7)$$

which is known as the differential entropy of Z (or f_Z).

Suppose we have a random object $(Z(u))_{u \in \mathcal{D}}$ distributed over a spatial domain $\mathcal{D}$. In that case, the bivariate (continuous) differential entropy can be computed between

two points with a lag separation $\mathbf{h}$. For instance, we can consider the joint differential entropy between $Z(\mathbf{u})$ and $Z(\mathbf{u} + \mathbf{h})$:

$$\begin{aligned} h(\mathbf{u}, \mathbf{u} + \mathbf{h}) &\equiv h(Z(\mathbf{u}), Z(\mathbf{u} + \mathbf{h})) = \\ &= -\int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} [\log f_{Z(\mathbf{u}), Z(\mathbf{u} + \mathbf{h})}(z, z')] f_{Z(\mathbf{u}), Z(\mathbf{u} + \mathbf{h})}(z, z') dz dz'. \end{aligned} \quad (8)$$

In a similar way to Eq.(4), the mutual information between $Z(\mathbf{u})$ and $Z(\mathbf{u} + \mathbf{h})$ is (Cover and Thomas 2006):

$$\begin{aligned} I(\mathbf{u}; \mathbf{u} + \mathbf{h}) &\equiv I(Z(\mathbf{u}); Z(\mathbf{u} + \mathbf{h})) \\ &= D\left(P_{Z(\mathbf{u}), Z(\mathbf{u} + \mathbf{h})} \parallel P_{Z(\mathbf{u})} \times P_{Z(\mathbf{u} + \mathbf{h})}\right) \end{aligned} \quad (9)$$

Entropy, Fig. 2 Maps of computed probabilities of prevalence of each category, using indicator simulation

$$= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \log \frac{f_{Z(\mathbf{u}), Z(\mathbf{u}+\mathbf{h})}(z, z')}{f_{Z(\mathbf{u})}(z)f_{Z(\mathbf{u}+\mathbf{h})}(z')} f_{Z(\mathbf{u}), Z(\mathbf{u}+\mathbf{h})}(z, z') dz dz'. \quad (10)$$

Applications

Characterizing Spatial Uncertainty

Entropy can be used as a measure of local uncertainty in a spatial context. In order to illustrate this notion, let us consider a simple two-dimensional domain, where a few locations have been sampled, and a category is assigned after logging or analyzing each sample (Fig. 1). These categories can be facies, rock types, or land use, for example. At unsampled locations, the uncertainty can be characterized in different ways. In this example, we calculate the entropy conditioned to the few logged (sampled) locations.

Indicator simulation is used to create multiple realizations of the categorical random function, from which the probability of each category prevailing at locations over the domain is calculated. Figure 2 shows the probability of finding each category at every location in the simulation grid. This result provides the conditional local probability mass distribution of the categorical variable at every unsampled location. We can compute the local entropy by applying Eq. 1. Figure 3 shows the map of local entropies. This map is consistent with the data and their spatial continuity. The high entropy values are located in areas with

higher uncertainty: in the contacts between the different categories and in areas poorly informed.

Maximum Entropy Principle for Sampling Design

From the previous analysis, entropy can be used to determine the sampling location that maximizes the information gain. This can be achieved by computing the Entropy before and after the sample is gathered. In a spatial model, it is important to notice that one sample will affect the uncertainty in neighboring locations. This influence is a function of the spatial correlation of the random function within the domain. Therefore, for sampling design, the decision does not seek the location with the highest entropy but rather the location that globally maximizes the reduction in entropy over the entire domain.

When a sampling network composed of r samples is needed, the problem becomes more complex, as the number of combinations to be assessed increases significantly with the number of samples r . Assuming there are n sample locations possible, the solution space becomes the combination $C(n, r)$, which rapidly becomes very large. Further strategies to deal with the sampling design problem are discussed in (Santibañez et al. 2019).

Entropy, Fig. 3 Map of local entropy computed from the conditional local probability mass function at every location

Summary and Final Remarks

Entropy is a fundamental tool to measure information content, uncertainty, or disorder. Its original formulation, originated in communication problems, has been adapted to be used in geoscience problems and expanded as a tool for spatial characterization.

Entropy is directly linked to information content and can be used as a metric for information gain, becoming a valuable tool to assess the value of new evidence (measurements).

Euler Poles of Tectonic Plates

Helmut Schaeben¹, Uwe Kroner¹ and Tobias Stephan²

Definition

Since Wegener's hypothesis of continental drift, geoscientists have developed a model of the Earth's evolution in terms of plate tectonics emphasizing horizontal motions of near-surface plates as opposed to vertical motions. Neglecting interactions of plates at their boundaries, their motions are bound to be rotations. A geometrically appealing and instructive parametrization of rotations is provided by their angles and axes, whose intersections with the sphere modeling the shape of the Earth are referred to as Euler poles. It seems tempting and challenging to represent the Earth's evolution in terms of interdependent transient rotations of a few major plates.

Introduction

The uppermost shell of the Earth, that is, the lithosphere, can be subdivided into several rigid, approximately 100-km-thick tectonic plates. These plates move over a weak mantle layer, the asthenosphere. Because of the differential kinematics, adjacent tectonic plates interact at their boundaries causing first-order geologic processes subsumed under the term global plate tectonics. There are three types of plate boundaries. Divergent plate boundaries, also called constructive plate boundaries, are characterized by the production of new lithosphere along a global system of mid-ocean ridges (MOR). Sea floor spreading at divergent plate boundaries is balanced by the consumption of lithosphere at convergent plate boundaries also referred to as destructive plate boundaries. At such a boundary, the leading edge of a tectonic lower plate subducts into deeper parts of the mantle beneath tectonic upper plates. Conservative plate boundaries are the third type of plate boundaries, lithosphere is neither generated nor consumed. Along transform faults, adjacent plates move laterally to each other thereby connecting segments of divergent and/or convergent plate boundaries. The modeling assumption of plate rigidity is not generally valid for its boundaries (Kreemer et al. 2014). Especially, convergent plate boundaries along continent-continent collision zones, that is, orogenic belts, are rather diffuse exhibiting a complex deformation pattern. Nevertheless, the geometry of the rigid parts of tectonic plates can be approximated by spherical polygons, their kinematics can be described in terms of rotations, their angles, and Euler poles, that is, the points of intersection of the axes of rotations and the sphere modeling the shape of the Earth (Bullard et al. 1965). Special attention is required to distinguish finite rotations from infinitesimal rotations. While finite rotations by a finite angle ω apply to represent rotational states, infinitesimal rotations by an infinitesimal small angle $\delta\omega$ refer to a (piecewise) circular motion. Most notably, infinitesimal rotations are commutative, finite rotations are not.

For the analysis of plate motions, an internal reference system and two external reference systems have been applied. Relative plate motions describe the kinematics of a pair of plates, one assumed to be moving and the other one assumed to be fixed. Then the fixed plate constitutes the reference system. In contrast, absolute plate motions reflect the movement of plates with respect to a global reference system. Classically, the deep mantle reference accounts for the absolute motion of the plates (DeMets et al. 1990) assuming a fixed system of hot spots (Morgan 1971) and thus a quasi-stationary mantle beneath the lithosphere. With the development of space geodesy, the International Celestial Reference Frame (ICRF) is available (www.iers.org) employing external quasi-stationary extragalactic sources, that is, quasars. The ICRF constitutes the reference system used by the satellites of the Global Positioning System (GPS) and allows for the

formulation of high precision earth model, that is, the International Terrestrial Reference Frame (ITRF). Analyzing the motion of GPS ground stations relative to the fixed Earth model results in plate kinematic models for recent times (Sella et al. 2002; Kreemer et al. 2014).

In terms of current plate motions, different plate kinematic models exist and thus different Euler pole solutions. Their differences originate from applying different reference systems, considering a different total number of plates and the limitations of the particularly specified data sets. For example, there is a significant deviation of global kinematics of absolute plate motions derived from the deep mantle reference system “HS3-NUVEL 1A” (Gripp and Gordon 2002) compared with global kinematics derived from the analysis of relative plate motions with “NUVEL 1A” (DeMets et al. 1994). The transformation from “HS3-NUVEL 1A” to “NUVEL 1A” requires an additional rotation of the entire lithosphere, that is, the net rotation. Plate kinematic models derived from space geodesy commonly assume no-net rotation, that is, the current motion of all points of the earth sums up to zero (Kreemer et al. 2014; Drewes 2009). In terms of rigid lithospheric plates, three adjacent plates P_1 , P_2 , P_3 meet at one common point, that is, the triple junction. Performing a plate circuit, that is, taking successively the plates P_i , $i = 1, 2, 3$, as fixed and watching each plate P_j , $j = 2, 3, 1$, moving according to an infinitesimal rotation by $\delta\omega$ relative to the fixed one about the axes $\mathbf{e}_{12}$, $\mathbf{e}_{23}$, $\mathbf{e}_{31}$ with rotation vectors (Euler vectors) $\boldsymbol{\omega}_{ij} = (\delta\omega)\mathbf{e}_{ij}$, the rotation vectors must sum up to zero (McKenzie and Morgan 1969; Le Pichon et al. 1973). To avoid any confusion, the plate circuit constraint is a mathematical property of infinitesimal rotations; it is not a geological property of tectonic plates. In general, plate circuits can be applied to several three-plate configurations each with a common triple junction. If the plate circuit constraint is valid for all configurations, the no-net rotation condition is fulfilled (DeMets et al. 1994).

To compare different plate kinematic models, the reader is referred to the plate motion calculator provided by UNAVCO (<https://www.unavco.org/software/geodetic-utilities/geodetic-utilities.html>).

Plate kinematic models of the past are much less precise due to the lack of space geodetic constraints. Moreover, constraints derived from the oceanic lithosphere are only available for Ceno- and Mesozoic times. Since almost all of the pre-Mesozoic oceanic lithosphere has been subducted at convergent plate boundaries, constraints for ancient plate kinematics are exclusively provided from the continental crust. Latitudinal information can be deduced from paleomagnetic, paleobiogeographic, and paleoclimatic studies (Scotese and McKerrow 1990). As with respect to the longitudinal position of the investigated region, information is not available. Hence, such data sets do not allow for an exact positioning of continental plates for various time steps and

thus for the formulation of precise plate kinematic models in pre-Mesozoic times, respectively. Euler poles of relative plate motions can be deduced from the spherical strain pattern of ancient plate boundary zones (Kroner et al. 2016) and have been applied for plate tectonic processes culminating in the late Paleozoic formation of the supercontinent Pangea (Kroner et al. 2016, 2020). Since such paleotectonic reconstructions initially consider plate motions relative to a fixed plate, the latitudinal positions of the continents must be approximated in a second step using appropriate data sets mentioned above.

Modeling the Geometry of Tectonic Plates and the Kinematics of Their Motion

Geometric Modeling of Tectonic Plates

The shape of the Earth is modeled as unit sphere $\mathbb{S}^2 \subset \mathbb{R}^3$ in three-dimensional Euclidean space. The geometry of the interior rigid core of tectonic plates is represented by spherical polygons, that is, closed geometric figures on the sphere, whose vertices are points of the sphere and whose edges are arcs of great circles connecting the vertices. In contrast to the Euclidean real plane, the complement of a spherical polygon is also a spherical polygon. Any motion of a rigid spherical polygon on the sphere is determined by rotations in $\mathbb{R}^3$. Euler’s theorem on rotations (Eulero 1775; Palais and Palais 2007) actually states that in three-dimensional Euclidean space, any rigid motion of a body leaving one of its points fixed is a unique rotation about some axis passing through the fixed point. This theorem implies that the sequential composition, that is, concatenation of two rotations, is a rotation, too. Euler’s theorem is the initializing account of modern mathematics of rotations (Goldstein 1950; Altmann 2013). Several parametrizations of a rotation exist; the parametrization in terms of its angle and axis appears self-evident, geometrically instructive, and practically appealing. In particular, it leads to an algebra to concatenate rotations explicitly in terms of unit quaternions.

Rotations in $\mathbb{R}^3$

In Euclidean geometry, a rotation is a linear transformation that preserves distances, that is, an isometry specified by its properties that it leaves at least one point fixed and that it preserves handedness. A rotation in three-dimensional Euclidean $\mathbb{R}^3$ is specified by an axis of its fixed points and an invariant plane of rotation orthogonal to that axis. Thus, a rotation R in $\mathbb{R}^3$ is uniquely defined in terms of its angle $\omega \in (-\pi, \pi]$ and its axis $\mathbf{e} \in \mathbb{S}^2$ of rotation, $R = R(\omega, \mathbf{e})$, as $R(\omega, \mathbf{e}) = R(-\omega, -\mathbf{e})$. The rotational axis passes through the center of the sphere and intersects the sphere at two antipodal points referred to as Euler poles in geology. Casually, Euler poles and axis of rotation provided by a unit vector are not distinguished here.

The terms are used synonymously and the common symbol is $\mathbf{e} \in S^2 \subset \mathbb{R}^3$. Keeping the angle ω of rotation fixed, the rotation $R(\omega, -\mathbf{e})$ is the inverse rotation of $R(\omega, \mathbf{e})$, that is, $R(\omega, -\mathbf{e})R(\omega, \mathbf{e}) = R(\omega, \mathbf{e})R(\omega, -\mathbf{e}) = \text{id}$, where id denotes the identical rotation by an angle $\omega = 0$.

According to Rodrigues' formula (Rodrigues 1840), applying the rotation $R(\omega, \mathbf{e})$ to the unit vector $\mathbf{u} \in S^2$ results in

$$R(\omega, \mathbf{e})\mathbf{u} = \mathbf{u} \cos \omega + (\mathbf{e} \times \mathbf{u}) \sin \omega + \mathbf{e}(\mathbf{e} \cdot \mathbf{u})(1 - \cos \omega) \quad (1)$$

$$= \mathbf{u} + (\mathbf{e} \times \mathbf{u}) \sin \omega + \mathbf{e} \times (\mathbf{e} \times \mathbf{u}) 2 \sin^2 \frac{\omega}{2}. \quad (2)$$

Otherwise, rotations in $\mathbb{R}^3$ may be expressed as (3×3) matrix of the special orthogonal group $\text{SO}(3)$ or as unit quaternion $q \in \mathbb{S}^3 \subset \mathbb{H}$, the skew field of real quaternions (Hamilton 1844),

$$q = \cos \frac{\omega}{2} + \mathbf{e} \sin \frac{\omega}{2}, \quad (3)$$

which seems to provide the most versatile and useful form close to the angle-axis parametrization, cf. Quaternions and Rotations, this Encyclopedia. Rodrigues formula, Eq. 1, is actually the result of the quaternion multiplication $q\mathbf{u}q^*$, where $\mathbf{u}$ is taken as pure unit quaternion and q^* denotes the conjugate unit quaternion of the unit quaternion q . Let the rotations $R_1 = R_1(\omega_1, \mathbf{e}_1)$ and $R_2 = R_2(\omega_2, \mathbf{e}_2)$ be associated with unit quaternions $q_1 = \cos \frac{\omega_1}{2} + \mathbf{e}_1 \sin \frac{\omega_1}{2}$ and $q_2 = \cos \frac{\omega_2}{2} + \mathbf{e}_2 \sin \frac{\omega_2}{2}$. Then, the concatenation $R = R(\omega, \mathbf{e}) = R_2(\omega_2, \mathbf{e}_2)R_1(\omega_1, \mathbf{e}_1)$ is associated with the quaternion product q_2q_1 .

$$\begin{aligned} q_2q_1 &= \cos \frac{\omega_2}{2} \cos \frac{\omega_1}{2} - \mathbf{e}_2\mathbf{e}_1 \sin \frac{\omega_2}{2} \sin \frac{\omega_1}{2} \\ &+ \mathbf{e}_1 \sin \frac{\omega_1}{2} \cos \frac{\omega_2}{2} + \mathbf{e}_2 \sin \frac{\omega_2}{2} \cos \frac{\omega_1}{2} + \mathbf{e}_2 \times \mathbf{e}_1 \sin \frac{\omega_1}{2} \sin \frac{\omega_2}{2}, \end{aligned} \quad (4)$$

and its scalar and vector part, respectively,

$$\cos \frac{\omega}{2} = \cos \frac{\omega_2}{2} \cos \frac{\omega_1}{2} - \mathbf{e}_2\mathbf{e}_1 \sin \frac{\omega_2}{2} \sin \frac{\omega_1}{2}, \quad (5)$$

$$\begin{aligned} \mathbf{e} \sin \frac{\omega}{2} &= \mathbf{e}_1 \sin \frac{\omega_1}{2} \cos \frac{\omega_2}{2} + \mathbf{e}_2 \sin \frac{\omega_2}{2} \cos \frac{\omega_1}{2} + \\ &\mathbf{e}_2 \times \mathbf{e}_1 \sin \frac{\omega_1}{2} \sin \frac{\omega_2}{2} \end{aligned} \quad (6)$$

provide the angle ω and the axis $\mathbf{e}$ of the rotation $R(\omega, \mathbf{e})$.

Whatever its form, a rotation as defined up to now is a transformation of coordinates. It describes a rotational state. It does not describe a dynamic process like a motion. There is no rationale yet of an angular velocity.

Kinematic Modeling of Plate Motion-Finite Rotations

Rotating a polygon P given by the sequence of its vertices $(\mathbf{u}_1, \dots, \mathbf{u}_n)$ results in the rotated polygon $P' = R(\omega, \mathbf{e})P$ with vertices $\mathbf{w}_i = R(\omega, \mathbf{e})\mathbf{u}_i$, $i = 1, \dots, n$, of the same shape and size as a rotation is first of all an isometry, that is, preserving distances. If a presumably unique rotation is initially unknown and only matched pairs $(\mathbf{u}_i, \mathbf{w}_i) \in S^2 \times S^2$ with $\mathbf{w}_i \approx R(\omega, \mathbf{e})\mathbf{u}_i$, $i = 1, \dots, n$, have been observed, then $R(\omega, \mathbf{e})$ can be estimated by spherical regression (MacKenzie 1957; Chang 1986, 1993; Meister 2001) where only the latter reference gives the solution in terms of quaternions.

Successive concatenation of a sequence of several rotations $R_\ell = R(\omega_\ell, \mathbf{e}_\ell)$, $\ell = 1, 2, \dots$, results in a sequence $(P, R_1P, R_2R_1P, \dots, R_\ell R_{\ell-1} \dots R_1P, \dots)$, of several rotational states. If the axes of rotations remain the same, $\mathbf{e}_\ell = \mathbf{e}$, $\ell = 1, 2, \dots$, then the ℓ -fold concatenation simplifies, that is, $R_\ell R_{\ell-1} \dots R_1 = R\left(\sum_{i=1}^{\ell} \omega_i, \mathbf{e}\right)$, $\ell = 1, 2, \dots$

Assigning increasing temporal marks $t_0 < t_1 < \dots < t_\ell < \dots$ to the rotational states, the association of every temporal mark t_ℓ to exactly one rotational state $R_\ell R_{\ell-1} \dots R_1P$ results in a time series, which in turn provides a first-order discrete model of a proceeding rotational motion of the polygon depending on the finite time lags $\Delta t_\ell = t_\ell - t_{\ell-1}$, $\ell = 1, 2, \dots$, in terms of a sequence of finite rotations describing the progressive change from one rotational state of the polygon to another rotational state. The first-order model immediately allows to calculate the rotation rate, that is, the magnitude $\frac{\omega_\ell}{\Delta t_\ell}$ of the vector $\boldsymbol{\omega}_\ell = \frac{1}{\Delta t_\ell} \boldsymbol{\omega}_\ell = \frac{\omega_\ell}{\Delta t_\ell} \mathbf{e}_\ell$ of the mean angular velocity over the time interval $(t_{\ell-1}, t_\ell]$, $\ell = 1, 2, \dots$. The magnitude of the corresponding mean linear velocity $\mathbf{v}_\ell$ along the small circle path of rotation with radius ρ is $\|\mathbf{v}_\ell\| = \frac{\omega_\ell}{\Delta t_\ell} \rho = \frac{\omega_\ell}{\Delta t_\ell} \sin \angle(\mathbf{e}_\ell, \mathbf{u}) = \|\boldsymbol{\omega}_\ell \times \mathbf{u}\|$. More generally, the rotations resulting from concatenation can be temporally indexed, for example, $R_\ell R_{\ell-1} \dots R_1 = R(\omega(t_\ell), \mathbf{e}(t_\ell))$, where $(\omega(t_\ell), \mathbf{e}(t_\ell))$ are the parameters of the ℓ -fold concatenation. If for all $\ell = 1, 2, \dots$ the axes of rotations are the same, $\mathbf{e}_\ell = \mathbf{e}$, then $\mathbf{e}(t_\ell) = \mathbf{e}$ and $\omega(t_\ell) = \sum_{i=1}^{\ell} \omega_i$. In this case, mean velocities $\frac{\omega(t_j) - \omega(t_i)}{t_j - t_i} = \frac{\sum_{\ell=i}^j \omega_\ell}{t_j - t_i}$ with respect to larger time intervals $(t_i, t_j]$ can be calculated analogously. Otherwise, these velocities are the apparent mean velocities referring to the small circle path of concatenated rotations. The true mean velocity during the period $(t_i, t_j]$ referring to the path composed of finite arcs of small circles of the sequence $(R_\ell, R_{\ell+1}R_\ell, \dots, R_{\ell_j} \dots R_{\ell_i+1}R_{\ell_i})$ of rotations can be calculated as the weighted mean of the individual arc-wise mean velocities.

Kinematic Modeling of Plate Motion-Infinesimal Rotations

A proceeding rotational motion is described by an infinitesimal rotation. If the angle of rotation is infinitesimal, $(\delta\omega) = O(\varepsilon)$, $0 \leq \varepsilon \ll 1$, then $\sin(\delta\omega) = (\delta\omega) + O(\varepsilon^3)$ and $\cos(\delta\omega) = 1 + O(\varepsilon^2)$, and the first-order approximation of $R(\omega, \mathbf{e})\mathbf{u}$ of Eq. 2 is

$$R((\delta\omega), \mathbf{e}) \mathbf{u} = \mathbf{u} + (\mathbf{e} \times \mathbf{u})(\delta\omega). \quad (7)$$

In contrast to finite rotations, infinitesimal rotations commute

$$R((\delta\omega), \mathbf{e}_2)R((\delta\omega), \mathbf{e}_1)\mathbf{u} = \mathbf{u} + (\mathbf{e}_1 \times \mathbf{u})(\delta\omega) + (\mathbf{e}_2 \times \mathbf{u})(\delta\omega) \quad (8)$$

$$= \mathbf{u} + ((\mathbf{e}_1 + \mathbf{e}_2) \times \mathbf{u})(\delta\omega) \quad (9)$$

$$= R((\delta\omega), \mathbf{e})\mathbf{u},$$

and their axes $\mathbf{e}_i$, $i = 1, 2$, sum to the axis $\mathbf{e} = \mathbf{e}_1 + \mathbf{e}_2$ of their concatenation, Eq. 9, that is, concatenation of rotations is turned into summation of their axes for infinitesimal rotations. Moreover, for infinitesimal rotations, the rotation vectors satisfy what is often referred to as closure constraint

$$(\delta\omega)\mathbf{e}_1 + (\delta\omega)\mathbf{e}_2 - (\delta\omega)\mathbf{e} = \boldsymbol{\omega}_1 + \boldsymbol{\omega}_2 - \boldsymbol{\omega} = 0, \quad (10)$$

that is, the three rotation vectors are coplanar.

The notion of an infinitesimal rotation gives rise to the infinitesimal generator of the group $SO(3)$ such that any finite rotation results from integrating the infinitesimal generator. Moreover, the notion of infinitesimal rotations applies to represent the motion of a rigid body driven by transient rotations in terms of a differential equation, where the path of the moving body is composed of infinitesimal small arcs of different small circles. A comprehensive and consistent dynamic model of the movement of tectonic plates throughout geological periods requires a representation in terms of differential equations involving infinitesimal rotations. To the best of our knowledge, such a model has still to be developed. Here it is sufficient to confine ourselves to finite rotations and time series of concatenated finite rotations.

Rotating Several Polygons

Rotating two polygons by a unique rotation, their relative location does not change, the effect of an isometry. That is to say that observed from one polygon, the other polygon is immobile. If two rotations are involved, each referring to one of the two polygons, which differ in their angles or axes of rotation, then the relative location of the two polygons does

no longer remain the same. In fact, if the two rotations differ in their (fixed) axes, then observed from one polygon, the other polygon is rotated by some angle about a migrating axis of rotation. The axes of rotations governing the motion of each polygon are referred to as absolute Euler poles; the migrating axis is referred to as relative Euler pole. If the two absolute Euler poles coincide, then the relative Euler pole coincides with the two. This setting is elaborated as follows.

Path of Migrating Euler Pole

At time t_0 , there are two spherical polygons $P_i(t_0)$, $i = 1, 2$. For the example given below, a single spherical triangle suffices to illustrate the migration. In the most simple case, two fixed Euler poles and corresponding axes of rotations $\mathbf{e}_i \in \mathbb{S}^2$, $i = 1, 2$, are assumed about which the polygons $P_i(t_0)$ are rotated by angles $\omega_i(t_\ell)$, respectively. Here t_ℓ is rather a parameter referring to a sequence $t_0 < t_1 < \dots < t_\ell < \dots$ than a continuous variable to suggest that the assumption of stationary absolute Euler poles could be dropped to get absolute Euler poles $\mathbf{e}_i(t_\ell) \in \mathbb{S}^2$ moving in time in the sense of concatenating finite rotations. In either case, at time $t_\ell > t_0$, there are two polygons $P_i(t_\ell)$, $i = 1, 2$,

$$P_i(t_\ell) = R_i(t_\ell)P_i(t_0) = R(\omega_i(t_\ell), \mathbf{e}_i(t_\ell))P_i(t_0), i = 1, 2. \quad (11)$$

The unique rotation $R(t_\ell) = R(\omega(t_\ell), \mathbf{e}(t_\ell)) = R_2(t_\ell)R_1^{-1}(t_\ell)$ about the migrating relative Euler pole $\mathbf{e}(t_\ell)$ by the angle $\omega(t_\ell)$ takes $P_1(t_\ell)$ to $\tilde{P}_1(t_\ell)$ where

$$\begin{aligned} \tilde{P}_1(t_\ell) &= R(\omega(t_\ell), \mathbf{e}(t_\ell))P_1(t_\ell) \\ &= R(\omega_2(t_\ell), \mathbf{e}_2(t_\ell))R(-\omega_1(t_\ell), \mathbf{e}_1(t_\ell))P_1(t_\ell) \\ &= R(\omega_2(t_\ell), \mathbf{e}_2(t_\ell))P_1(t_0). \end{aligned} \quad (12)$$

Obviously, the relative location of the polygons $P_2(t_\ell)$ and $\tilde{P}_1(t_\ell)$ is the same as of the initial polygons $P_2(t_0)$ and $P_1(t_0)$ as the latter polygons were subject to the same rotation $R(\omega_2(t_\ell), \mathbf{e}_2(t_\ell))$. In turn, observed from polygon $P_2(t_\ell)$ (apparently immobile), polygon $P_1(t_\ell)$ is rotated by $R(t_\ell) = R_2(t_\ell)R_1^{-1}(t_\ell)$ or, equivalently, polygon $\tilde{P}_1(t_\ell)$ is rotated by $R^{-1}(t_\ell) = R_1(t_\ell)R_2^{-1}(t_\ell)$.

Angle and axis of $R(t_\ell)$ are given as follows. If the axes of rotations $\mathbf{e}_1(t_\ell)$ and $\mathbf{e}_2(t_\ell)$ are identical, the solution for $R(t_\ell)$ is trivial, that is, $\mathbf{e}(t_\ell) = \mathbf{e}_1(t_\ell) = \mathbf{e}_2(t_\ell)$ and $\omega(t_\ell) = \omega_2(t_\ell) - \omega_1(t_\ell)$. If $\mathbf{e}_1(t_\ell)$ and $\mathbf{e}_2(t_\ell)$ are stationary, so is $\mathbf{e}(t_\ell)$. If the two absolute Euler poles are assumed to be different, $\mathbf{e}_1(t_\ell) \neq \mathbf{e}_2(t_\ell)$, then the solution is a straightforward application of concatenation in terms of unit quaternions (Altmann 2013, Kuipers 1999, Quaternions and Rotations, this Encyclopedia) with $q_i(t_\ell) =$

$\cos\left(\frac{\omega_i(t_\ell)}{2}\right) + \mathbf{q}_i(t_\ell)$ and $\mathbf{q}_i(t_\ell) = \sin\left(\frac{\omega_i(t_\ell)}{2}\right) \mathbf{e}_i(t_\ell)$, $i = 1, 2$, and $\mathbf{q}_1^*(t_\ell) = \sin\left(\frac{-\omega_1(t_\ell)}{2}\right) \mathbf{e}_1(t_\ell) = -\sin\left(\frac{\omega_1(t_\ell)}{2}\right) \mathbf{e}_1(t_\ell)$

$$\omega(t_\ell) = 2 \arccos \left(\cos \left(\frac{\omega_2(t_\ell)}{2} \right) \cos \left(\frac{\omega_1(t_\ell)}{2} \right) - \mathbf{q}_2(t_\ell) \cdot \mathbf{q}_1^*(t_\ell) \right) \quad (13)$$

$$\mathbf{e}(t_\ell) = \frac{1}{\sin \frac{\omega(t_\ell)}{2}} \left(\mathbf{q}_1^*(t_\ell) \cos \left(\frac{\omega_2(t_\ell)}{2} \right) + \mathbf{q}_2(t_\ell) \cos \left(\frac{\omega_1(t_\ell)}{2} \right) + \mathbf{q}_2(t_\ell) \times \mathbf{q}_1^*(t_\ell) \right). \quad (14)$$

It is emphasized that the relative Euler pole $\mathbf{e}(t_\ell)$ is migrating even if the two absolute Euler poles $\mathbf{e}_1(t_\ell)$ and $\mathbf{e}_2(t_\ell)$ are stationary.

If the two absolute Euler poles $\mathbf{e}_1(t_\ell)$ and $\mathbf{e}_2(t_\ell)$ are assumed to be stationary, that is, $\mathbf{e}_i(t_\ell) = \mathbf{e}_i$, $i = 1, 2$, and if $|\omega_1(t_\ell)| = |\omega_2(t_\ell)|$ is assumed, the former equations, Eqs. (13) and (14), simplify to

$$\omega(t_\ell) = 2 \arccos \left(\cos^2 \left(\frac{\omega_1(t_\ell)}{2} \right) - \mathbf{q}_2(t_\ell) \cdot \mathbf{q}_1^*(t_\ell) \right) \quad (15)$$

$$\mathbf{e}(t_\ell) = \frac{1}{\sin \frac{\omega(t_\ell)}{2}} \left((\mathbf{q}_1^*(t_\ell) + \mathbf{q}_2(t_\ell)) \cos \left(\frac{\omega_1(t_\ell)}{2} \right) + \mathbf{q}_2(t_\ell) \times \mathbf{q}_1^*(t_\ell) \right). \quad (16)$$

Since the assumption of stationary rotation axes implies that the directions of $\mathbf{q}_1$ and $\mathbf{q}_2$ are stationary, Eq. (16) reveals that if

(i) $\omega_2(t_\ell) = \omega_1(t_\ell)$, the migrating relative Euler pole is an element of the intersection of the plane spanned by $\mathbf{e}_2 - \mathbf{e}_1$ and $\mathbf{e}_2 \times \mathbf{e}_1$ and the unit sphere $\mathbb{S}^2 \subset \mathbb{R}^3$, (ii) $\omega_2(t_\ell) = -\omega_1(t_\ell)$, the migrating relative Euler pole is an element of the intersection of the plane spanned by $\mathbf{e}_1 + \mathbf{e}_2$ and $\mathbf{e}_1 \times \mathbf{e}_2$ and the unit sphere $\mathbb{S}^2$, that is, the relative Euler pole migrates along a great circle in both cases. Thus, it proves what Fig. 1 suggests that for angles $|\omega_1(t_\ell)| = |\omega_2(t_\ell)|$, that is, for equal angular velocities, the relative Euler pole $\mathbf{e}(t_\ell)$ migrates either along the great circle $C\left(\frac{\mathbf{e}_2 - \mathbf{e}_1}{\|\mathbf{e}_2 - \mathbf{e}_1\|}, \frac{\mathbf{e}_2 \times \mathbf{e}_1}{\|\mathbf{e}_2 \times \mathbf{e}_1\|}\right)$ or along the great circle $C\left(\frac{\mathbf{e}_1 + \mathbf{e}_2}{\|\mathbf{e}_1 + \mathbf{e}_2\|}, \frac{\mathbf{e}_1 \times \mathbf{e}_2}{\|\mathbf{e}_1 \times \mathbf{e}_2\|}\right)$, both orthogonal to the great circle $C(\mathbf{e}_1, \mathbf{e}_2)$ spanned by the two fixed absolute Euler poles $\mathbf{e}_1$ and $\mathbf{e}_2$. Figure 1 also confirms that for an infinitesimal angle $\delta\omega$, the relative Euler pole and the two absolute Euler poles are coplanar. Moreover, Eqs. (13) and (15), respectively, indicate that the velocity of the migration is not constant.

Equations (13) and (14) are easily generalized to consider Euler poles $\mathbf{e}_1(t)$, $\mathbf{e}_2(t)$ moving with respect to finite time steps by means of concatenating finite rotations. The path of migration of the Euler pole $\mathbf{e}(t)$ will be more involved than arcs along a unique great circle. To represent the path of the continuously migrating Euler pole corresponding to rotations with both their parameters varying continuously with time requires the solution of a differential equation involving infinitesimal rotations.

The geometric setting can be generalized to N different polygons and $M \leq N$ different Euler poles of their authorized rotations. For N different polygons, there are $\frac{(N-1)N}{2}$ pairs of different polygons. The relative motion of the two polygons of a pair is governed by rotations with a migrating Euler pole if the two corresponding absolute Euler poles are different.

Euler Poles of Tectonic Plates, Fig. 1 Equal angle projection of upper hemisphere

Left: Initially, the green and the red triangle are close to each other with one edge almost adjacent. Then they are successively rotated, in the sense of finite rotations, the green triangle counter-clockwise by $\omega_1, \omega_2, \dots, \omega_5$ about its fixed absolute Euler pole $\mathbf{e}_1$ (green dot) and the red triangle clockwise by $-\omega_1, -\omega_2, \dots, -\omega_5$ about its fixed absolute Euler pole $\mathbf{e}_2$ (red dot). Watching the sphere from outside, the triangles' vertices apparently move along arcs of small circles colored green or red, respectively, centered at their corresponding fixed absolute Euler poles $\mathbf{e}_1$ and $\mathbf{e}_2$, respectively. Both the absolute and the relative locations of the triangles are changing. Center: To preserve the relative location of the rotated green triangles with respect to the rotated red triangles, the vertices of the green triangles

have apparently to move along arcs of small circles colored blue centered at their corresponding relative Euler poles $\mathbf{e}(t_\ell)$ (blue dot) migrating along a great circle orthogonal to the great circle spanned by the two fixed axes $\mathbf{e}_1$ and $\mathbf{e}_2$. That is, when watching the rotated green triangles from the rotated red triangles assumed to be immobile, the green triangles appear to be rotated about the migrating relative Euler poles $\mathbf{e}(t_\ell)$ (blue dot). For an infinitesimal angle $\delta\omega$, the three axes $\mathbf{e}(t_\ell)$, $\mathbf{e}_1$, and $\mathbf{e}_2$ are coplanar and located on the great circle spanned by the two fixed axes $\mathbf{e}_1$ and $\mathbf{e}_2$.

Right: If the red triangle is rotated clockwise by $-3\omega_1, -3\omega_2, \dots, -3\omega_5$ about its fixed absolute Euler pole $\mathbf{e}_2$ (red dot), then the relative Euler poles $\mathbf{e}(t_\ell)$ (blue dot) of the apparent motion of the green triangles as watched from the red triangles do not migrate along a great circle.

Conclusions

Finite and infinitesimal rotations must not be confused. Only the infinitesimal rotations give rise to the global plate circuit closure as applied in space geodesy focusing on the determination of the plates' velocities today. In geology/tectonics, emphasis is put on how plates have moved, that is, on how the locations of the plates have changed over geological times of hundreds of millions years. Since the change of locations can be associated with different rotational states, finite rotations by large angles of Euler poles apply to represent the motion of plates. As shown, for a set of stationary absolute Euler poles, the resulting relative Euler poles migrate in a complex manner with time. Dropping the assumption of stationary absolute Euler poles, the complexity of the plates' motion increases further and requires more involved models than presented here.

Expectation-Maximization Algorithm

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

Expectation-maximization (EM) is a methodology for estimating parameters of statistical models of data from observed samples using an iterative approach (Moon 1996; Do and Batzoglou 2008). As the name suggests, the EM algorithm may include several instances of statistical model parameter estimation using observed data. However, it has come to be used widely in clustering and classification methods, which are predominantly covered in this chapter.

The algorithm was named as such in the seminal paper, also referred to as Dempster–Laird–Rubin method (Dempster et al. 1977), where it has been built on similar existing methods. This paper had generalized the algorithm for several problems and provided the convergence analysis of the iterative method. The paper refers to observations as *incomplete data*, represented using two sample spaces $\mathcal{X}$ and $\mathcal{Y}$, and a many-to-one mapping from $\mathcal{X}$ to $\mathcal{Y}$. The observed data is the set $\mathbf{y} \subset \mathcal{Y}$, and its corresponding data vector to infer $\mathbf{x} \subset \mathcal{X}$ is indirectly observed or realized through $\mathbf{y}$. The complete family of sampling density is given by $f(\mathbf{x}|\boldsymbol{\phi})$, and that for the incomplete data is $g(\mathbf{y}|\boldsymbol{\phi})$, where $\boldsymbol{\phi}$ is the set of parameters for a mixture model that models the sample spaces. The assumption made here is that the observed data is sampled from a larger dataset that can have different subpopulations modeled using a different statistical model. The relationship is given as $g(\mathbf{y}|\boldsymbol{\phi}) = \int_{\mathbf{x}(\mathbf{y})} f(\mathbf{x}|\boldsymbol{\phi})d\mathbf{x}$. The EM algorithm is motivated to estimate $\boldsymbol{\phi}$ that maximizes $g(\mathbf{y}|\boldsymbol{\phi})$.

Overview

The EM algorithm is usually defined with the exponential family of distributions, notably the Gaussian or normal distribution. Thus, often the EM algorithm is described with the use of Gaussian mixture model (GMM). For parameter estimation, the EM algorithm has two steps in each iteration: expectation (E-step) and maximizations (M-step). The complete data is now defined using exponential family:

$$f(\mathbf{x}|\boldsymbol{\phi}) = b(\mathbf{x}) \exp(\boldsymbol{\phi} \cdot \mathbf{t}(\mathbf{x})^T) / a(\boldsymbol{\phi}),$$

where the vectors $\boldsymbol{\phi}$, $\mathbf{t}(\mathbf{x}) \in \mathbb{R}^1 \times r$ and T is the matrix transpose.

The i th iteration is defined as

E-step Estimating the complete data *sufficient statistics* $\mathbf{t}(\mathbf{x})$ using

$$Q(\mathbf{t}|\mathbf{t}^{(i)}) = \mathbf{t}^{(i)} = E(\mathbf{t}(\mathbf{x})|\boldsymbol{\phi}^{(i)}).$$

M-step Determining the parameter

$$\begin{aligned} E(\mathbf{t}(\mathbf{x})|\boldsymbol{\phi}) &= \mathbf{t}^{(i)}, \text{ achieved by maximization of } Q, \boldsymbol{\phi}^{(i+1)} \\ &= \arg \max_{\boldsymbol{\phi}} Q(\boldsymbol{\phi}|\boldsymbol{\phi}^{(i)}). \end{aligned}$$

The iterations are terminated when there is no change in the parameters, thus indicating a stable solution.

The function $\mathbf{x}$ can use the maximum likelihood (ML) function $\mathcal{L}(\boldsymbol{\phi}, \mathcal{X}, \mathcal{Y})$, for which log-likelihood function is best suited. The log-likelihood function has the desirable property of its derivative being expressed as the difference of an unconditional and a conditional expectation of the sufficient statistics (Dempster et al. 1977). Since there is no guarantee of a global maximum, local maximum values are determined. Also, there has been relevant work where maximum a posteriori (MAP) estimate has been used instead of ML function.

For mixture models, the mixing proportion value α_i must be determined for $i = 1, \dots, m$ components.

$$f(\mathbf{x}|\boldsymbol{\phi}) = \sum_{i=1}^m \alpha_i f_i(\mathbf{x}|\boldsymbol{\phi}_i), \text{ for } f_i \text{ which are individual model}$$

descriptions. A detailed description of a working toy example of the implementation of the EM algorithm is given by Plasse (2013). The implementation involves an initial assumption for the following values: (i) mixing proportion α_i , (ii) mean or the average μ_i of subpopulation in each component, and (iii) covariance matrix Σ_i to be the estimated and updated values in each step until the separated components are achieved in a

few iterations. An appropriate initialization can help reduce the number of iterations. Initialization can be improved by using conventional clustering algorithms, e.g., K-means clustering, to roughly estimate the subpopulations in components.

Figure 1 demonstrates the implementation of the EM algorithm using the Python library `sklearn` on the Iris dataset, which is a toy example of mostly well-separated clusters. Depending on the number of variables in the observed data, the functions used are usually multivariate Gaussian distributions to improve the model approximation (Do and Batzoglou 2008). The EM algorithm works best with well-separated clusters, without the requirement of circular-shaped clusters, as is the case for K-means clustering, when using Euclidean distance. However, it does not work effectively for ill-separated clusters, as shown in Fig. 2. The degree of class separability is reflected by the cluster separability, and thus, influences the number of iterations for convergence. More iterations are needed for ill-separated clusters than for the well-separated ones. Depending on the degree of class separability, acceleration methods, such as the ones used for fixed-point iteration, enable reducing the number of iterations needed for convergence (Plasse 2013).

Here, the *Iris* and *Forest cover-type* datasets, which are widely used machine learning datasets, are studied in Figs. 1 and 2. The *Iris* dataset includes physical dimensions of samples of different flowers belonging to the three species of the *Iris* family. The *Forest cover-type* dataset includes cartographic variables captured for each observed sample in 30×30 meter cell, obtained in the US Forest Service (USFS) Region 2 Resource Information System. The data for these variables have been procured from both the US Geological Survey (USGS) and USFS data sources for the samples collected from four different wilderness areas. The *Iris* dataset has one class that is linearly separable from the other two, which improves the degree of separation of clusters. In the *Forest cover-type* dataset, the wilderness areas are statistically significant for classification. However, since these areas are represented as categorical variables and not numerical variables, the EM algorithm does not work efficiently in its direct form with the less significant numerical variables. In such cases, the EM algorithm has to use the ML estimation used for mixed continuous and categorical data (Little and Schluchter 1985). The ML estimates used here are for a parameterization of the joint distribution of continuous and categorical variables in incomplete data.

Applications with Focus on Remotely Sensed Images

Apart from identifying the parameters to determine the mixture models of observed data, the EM algorithm also enables

Expectation-Maximization Algorithm, Fig. 1 Using `sklearn` package in Python, the Gaussian mixture model produces clusters as shown, where the clustering changes iteratively before stabilizing at the ninth iteration for the *Iris* dataset. The colors distinguish the clusters

alone and are not tagged to specific clusters. The ellipses indicate the Gaussian functions, their mean, and variance. (Image source: author's own; dataset source: <https://archive.ics.uci.edu/ml/datasets/iris>)

knowledge discovery. Several processes tend to have latent variables, which can be discovered by explicitly including them in the model without the knowledge of their statistical significance. In addition to the tabular or multivariate data in the toy examples in Figs. 1 and 2, the EM algorithm is widely used with image data. Image processing applications use the algorithm to determine class probabilities and classify the pixels in the images for semantic segmentation, or the images themselves. A set of representative diverse applications in the use of EM algorithm for remotely sensed images is reported in this chapter.

For data fusion needed for classification of multitemporal multisource remote sensing images, the temporal correlation between images is used for computing prior joint probabilities of classes, further estimated using a modified variant of the EM algorithm (Bruzzone et al. 1999). The EM algorithm, thus, has been used to alleviate the need for a human expert to compute these prior joint probabilities. The guarantee of convergence of the EM algorithm to a local maximum of the

ML function enables getting accurate estimates of the probabilities. In this work, the probabilities are used in a classifier, specifically, the multilayer perceptron neural network.

In a similar way, the EM algorithm can be used for change detection applications, where the pixel-wise discrimination of change requires the statistical distribution of “changed” and “unchanged” pixels in a difference image between two time stamps (Bruzzone and Prieto 2000). The use of the EM algorithm for this application has been implemented under the assumption that the conditional density functions of the classes in the difference image can be approximately modeled by GMMs. In this work, the semantic segmentation of changed pixels in the difference images has been further used for thresholding and change detection estimation error computation. Extending this work, the change detection modeled using the EM algorithm in the difference image from multitemporal remote sensing images is then subjected to a level-set method for unsupervised classification (Hao et al. 2013).

Expectation-Maximization Algorithm, Fig. 2 Comparison of well- and ill-separated classes demonstrated in the two-dimensional projection of the (i) Iris and (ii) Forest cover-type datasets, respectively. The conventional EM algorithm is well- and ill-suited for clustering in these cases, respectively. The visualizations were generated using

matplotlib in Python using two of the numerical attributes that have been found statistically significant in clustering using exploratory data analysis. (Image source: author's own; dataset source: <https://archive.ics.uci.edu/ml/datasets/iris> and <https://archive.ics.uci.edu/ml/datasets/Covertype>)

Summary

The EM algorithm is an effective method for estimating statistical distributions that enable data mining processes, such as classification and clustering. This has widespread applications in geoscience. Owing to the stability and convergence of its iterative implementation, the EM algorithm continues to be widely used in the geoscientific data processing.

Geochemical prospecting

Definition

The application of geochemical techniques and data analysis methods to the discovery of new mineral deposits and energy resources.

Introduction

Exploration geochemistry involves the assessment of chemical and mineralogical data obtained from a variety of sampling media to locate new mineral deposits and energy resources. In the case of mineral deposits this includes characterizing and modeling geochemical patterns and processes within the primary environment (alteration of the lithological hosts to mineral deposits and the mineralization itself) and the secondary environment (the weathered zone into which elements may disperse or in which secondary mineral deposits may form). A wide range of statistical and spatial analysis techniques may be applied to geochemical data to help identify, isolate, and map geochemical patterns related to the influence of mineralization.

The process of mineralization and associated alteration or the lateral geochemical dispersion of elements in either environment generates atypical geochemistry and mineralogy. The design of geochemical exploration program must therefore encompass the selection, measurement, mapping, and modeling of geochemical features that most effectively separate such atypical or anomalous geochemical patterns from those characteristic of unmineralized (background) zones. Ideally, the analysis or modeling of the geochemical data does not just create a binary categorization of samples or areas into background or anomalous clusters (with associated probabilities of membership), but also provides indicators of the proximity to mineralization via geochemical gradients from which vectors toward mineralization can be established.

Most geochemical datasets currently used in mineral exploration are multivariate. There is increasing use of statistical methods that address multidimensional space to detect and isolate patterns that reflect various geochemical processes (including mineralization) that produce concentration changes in groups of elements. These generally prove more effective than univariate methods in detecting subtle mineralization signatures and providing more reliable probabilistic predictive maps (Grunsky and Caritat 2020).

Historical Developments

Beyond simple visual assessment of spatial geochemical patterns, early statistical approaches focused on simply detecting individual element enrichment or depletion. Univariate anomalies were defined as observations with a low probability of being part of the expected background population – including the assumption that such populations were parametric. Threshold values were set and different populations separated and characterized using graphical techniques such as probability or quantile-quantile plots.

Advances in analytical methods that provide lower detection limits (resulting in a reduction in the proportion of “left-censored” data) provided greater understanding on the factors controlling variability in background patterns, especially for the precious and platinum group elements. “Anomalism” would need to be defined against a highly variable background (Reimann and Garrett 2005) reflecting variation in parent lithology, regolith-landform formation processes, controls on element mobility, and other factors that can exert significant influence on trace and major elements in the primary or secondary environment and spatial discontinuities at various scales.

From the early 1980s onward, the general availability of hardware and software capable of undertaking complex multivariate modeling, simulations, and visualization of data, along with developments of new parametric and nonparametric statistical methods, invited a revisitation to the fundamental question for exploration geochemists – “what is a geochemical anomaly?”. This has resulted in an evolution in the analysis of geochemical data from finding “satellites” (outlying values distant from the main cluster of observations) to detecting more subtle (multivariate) patterns related to the geochemical effects of mineralization, and associated clustering of samples or associations between variables within the main body of observations.

Univariate and Bivariate Methods

There are many approaches to identification of anomalous observations and the separation and characterization of different overlapping populations. This has included the setting of arbitrary boundaries to assumed probability distributions, of which the normal distribution (or distribution transformed to normality) has dominated and linked to tests of significance, outside of which an observation is assigned a high chance of being anomalous. Various rank-order criteria and boundaries have also been used, such the inner or outer fences of Tukey boxplots, as they are less influenced by extreme values in datasets.

There are a number of controls on the physical (mechanical) and chemical (hydromorphic) dispersion of elements and minerals from deposits in the secondary environment. These vary substantially between elements and environments, but can be quantified using appropriate geochemical models. Examples include the effects of stream energy on the relative abundance of heavy minerals (e.g., gold grains or cassiterite) and the incorporation of various chalcophile or siderophile metals within secondary Fe(III) oxides in soils and sediments. Geochemical patterns related to the influence of mineralization must be separated from such

Exploration Geochemistry, Fig. 1 Enhanced anomalous dispersion patterns of Pb in lag by regressing out the effects of variation in Fe. (Data from Dunlop et al. 1983)

local environmental factors. The use of various forms of regression analysis has been common. An example is the effect “regressing out” the influence of variation in Fe in the concentration of Pb incorporated into clasts collected from drainages surrounding the Elura Ag-Pb-Zn sulfide deposit. The resulting Pb residuals display a more distinct and coherent set of anomalies downstream of the deposit and subdued response in other sub-catchments (Fig. 1).

Geochemical data commonly display fractal or multifractal behavior in response to changes in metal sources or variations in the geochemical landscape at various scales. Fractal analysis has progressively overtaken other methods to split populations and identify anomalous populations within geochemical data.

Multivariate Methods

A wide range of multivariate methods have been applied to exploration geochemical data with the object of pattern recognition, clustering of variables and samples (R-mode and Q-mode) and anomaly detection through the isolation and enhancement of patterns associated with the effects of mineralization and identifying samples exhibiting such patterns. Most mineral deposits styles involve enrichment (or depletion) of suites of elements resulting in distortion or clustering of element relationships in the resultant multidimensional space, or separation of populations due to the effects of mineralization and the resulting highly atypical geochemistry of most sampling media. This yields many advantages of multivariate over univariate statistical and data visualization methods, not the least being a greater capacity to detect subtle influences of mineralization on regolith in areas of deep weathering or where surface materials have been transported.

Exploration Geochemistry, Fig. 2 (a) PER for samples from various intermediate to felsic intrusive units in the Collahuasi District of northern Chile ratioed against a conserved element (Zr) with selected mineral control lines and (b) Plot of an alteration index reflecting mass transfer

Geochemical data can also be projected into mineralogical space by conversion of mass abundances to molar abundances (with or without normalization against conserved elements) and the selection of suitable axes that reflect mineral compositions. The use of Pearce element ratio (PER) diagrams is one example that has been used to measure the extent and nature of rock alteration, and the relationship to the abundance of elements of economic interest (Stanley 2018). In a case study on the Collahuasi District of northern Chile (Urqueta et al. 2009), the degree of hydrolytic alteration in intrusive units (loss of Ca and Na and/or gain of K) was quantitatively related to the distance of observations from the feldspar control line along which samples with no alteration would plot (Fig. 2). In this and other studied the extent and nature of such alteration is more effectively and efficiently represented in the geochemical data than petrological examination in the field or laboratory and assists vectoring to mineralization based on varying alteration intensity.

Most geochemical datasets used in mineral exploration involve total or selectively extracted elemental abundances. Statistical methods applied to such compositional data are subject to the potential biasing effects of data closure. A number of corrections can be applied to reduce closure effects, for which the use of component ratios to open the data into real number space are commonly applied, such as

under hydrolytic alteration for samples based on a distance metric of observations from the feldspar control line (unaltered samples). (After Urqueta et al. 2009)

the additive, centered, and isometric log-ratios log-ratio (*alr*, *clr*, and *ilr*) (Buccianti and Grunsky 2014). This pre-processing of data can also reduce the effects of skewed distributions or outliers on classical multivariate methods such as principal components analysis, factor analysis, and other methods involving decomposing of variance-covariance or correlation matrices.

As an example, factor analysis was applied to multi-element data in soils collected from a grid across the basaltic pillow and basal lavas that host a number of VHMS Cu deposits in Cyprus. A six-factor model (with varimax rotation) was applied to both $\log_{10}$ -transformed data to reduce the effects of outliers and non-normal distribution on the model and *clr*-transformed data that also reduce the effects of data closure. Both approaches delivered factors displaying moderate to strong factor loadings for some chalcophile elements, although the *clr*-transformed data displayed more of these with a loading >0.4). However, the *clr*-transformed data displayed stronger separation between areas with known mineralization (high sample factor scores) in terms of both geochemical contrast (numerical differences between mineralized and background areas) and spatial coherence of the patterns (Fig. 3).

Exploration Geochemistry, Fig. 3 Comparison of mineralization-related factor score patterns and known Cyprus-style VMS Cu deposits in factor analysis of $\log_{10}$ -transformed and centered-log ratio

transformed multivariate geochemical data in soils overlying basaltic pillow lavas of the Troodos Ophiolite. (Data from Cohen et al. 2012)

Spatial Methods

Two features common to most exploration geochemical datasets are that (i) samples are spatially related in two or three dimensions and (ii) sampling is very limited or even skeletal compared with the complexity and scale of the entities that such data is being used to characterize (Cheng 1999). Geostatistical techniques have long been used to quantify the relationship between distance between samples and the associated variance of geochemical attributes, with applications in ore reserve estimation and in conversion of point data to spatially continuous variables (e.g., rasterizing). It remains an essential step in the systematic analysis of geochemical mapping data to spatially correlate observed or extracted patterns with other relevant spatial datasets including regional and local geology, regolith-landform maps, and other relevant spatial information. This can be accomplished within various GIS platforms (Carranza 2008).

Univariate or multivariate geochemical anomaly delineation techniques that incorporate spatial variability and correlation among samples, along with frequency distributions, are defined as structural approaches (Reimann et al. 2011). They assist the setting of criteria for defining anomalous geochemical signatures that better reflect variations in local geology,

regolith-landform setting, and other features that can exert substantial control on the geochemistry of media such as soils and stream sediments. Structural methods include a variety of fractal techniques (e.g., concentration-area), U-statistics, and singularity analysis among others (Geranian et al. 2013; Liu et al. 2017; Ghezelbash et al. 2019).

An example is drawn from bulk leach-extractable and $< 180 \mu\text{m}$ fraction Au contents in stream sediments from a large region of western Turkey (Yilmaz et al. 2017). Using a concentration-area fractal model $A(c \geq c_i) \propto c_i^{-D}$, where $A(c \geq c_i)$ represents the area (A) with concentrations $\geq$ to contour value c_i and D is the fractal dimension, both geochemical variables displaying fractal behavior. Known mineralized catchments are associated with the upper two fractal populations and a number of new areas with mineral potential were identified (Fig. 4).

Directions

On-going developments in sampling and analytical methods, including progressive lowering of detection limits, access to methods for routine analysis of a wider range of isotopes or chemical species, and understanding geochemical processes

Exploration Geochemistry, Fig. 4 Comparison of concentration-area fractal populations in BLEG and < 180 μm fraction Au in stream sediments from central-western Turkey. (After Yilmaz et al. 2017)

controlling dispersion in the primary and secondary environments are providing new dimensions to geochemical data and capacity to predict the form that geochemical anomalies might take. The evolution of statistical methods is towards techniques that are able to separate complex multivariate patterns within geochemical data and isolate the signal(s) that relate to the effects of mineralization based on the inherent characteristics of the data rather than preconceived models or assumptions. This will be facilitated by advances in the broad field of supervised and unsupervised machine learning approaches capable of modeling complex multivariate geochemical distributions and identifying latent associations between variables and samples (Zuo 2017) and other feature extraction and selection techniques (Zekri et al. 2019). Specific techniques include artificial neural networks, support vector machines, and random forests.

Deep learning algorithms are proving more effective in dealing with complex datasets that could enhance the geochemical anomaly detection and help in identifying hidden geochemical patterns in data. Deep machine learning architectures include stacked auto-encoding, convolutional and recurrent neural networks, and generative adversarial networks (Zuo et al. 2019). Exploration geochemistry utilized

by various machine learning methods have growing roles in mineral prospectivity mapping, especially areas where mineralization displays very weak surface expression.

Summary

The principal objective of exploration geochemistry is to define areas, at regional to mineral deposit scales, that have high probability of containing mineral deposits of the style and size required. This is largely dependent on the selection and application of numerical criteria to the distribution characteristics of individual variables, patterns of correlation between variables, spatial patterns within geochemical (and associated) datasets, capable of isolating patterns and signals associated with the effects of mineralization (anomaly identification) from other factors (background characterization).

Exploratory Data Analysis

Emmanuel John M. Carranza

Department of Geology, Faculty of Natural and Agricultural Sciences, University of the Free State, Bloemfontein, Republic of South Africa

Definition

Exploratory data analysis (hereafter denoted as EDA) is not a technique but it is a paradigm or strategy for robust analysis of data (Tukey 1977). It comprises descriptive, statistical, and, largely, graphical investigations meant for (a) obtaining the greatest understanding of a set of data, (b) revealing structure of data, (c) determining important data variables, (d) determining outlying and anomalous values in the data, (e) proposing and examining hypotheses, (f) creating judicious models, and (g) identifying optimum way(s) to manage and analyze data. It is a vigorous initial phase of data analysis prior to their treatment, for the purpose the data were to be used, by applying other methods of statistical analysis.

Introduction

The progression of EDA is from problem to data to analysis to model to conclusion. This contrasts with the progression of data analysis in classical statistics, which is from problem to data to model to analysis to conclusion. The progression of EDA also differs with the progression of data analysis in probabilistic framework, which is from problem to data to model to analysis of a priori data distribution to conclusion. Therefore, whereas data analyses in classical statistical and probabilistic frameworks are confirmatory in nature because they require models of prior assumptions of data distribution, EDA is, by virtue of its name, exploratory in nature.

EDA has four main aspects (cf. Tukey 1977; Howarth 1984): (a) graphical analysis to unravel data structure; (b) data transformation to simplify data behavior; (c) application of resilient techniques that are not overly affected by a few outlying values; and (d) focus on residual values, i.e., some portion of the data not accounted for by a certain model. The objective of EDA is, therefore, to identify “theoretically explainable” but often not obvious patterns in data (Good 1983) by way of using resilient and robust tools for descriptive and graphical statistical analyses that are different from those used for classical statistical analysis. A statistic is resilient and robust if it is only faintly influenced (a) by either a few gross errors or several small errors (resilience) and (b) by outlying values (robustness). In EDA, the tools employed for descriptive statistical and graphical

analyses are not according to a model of data frequency distribution (e.g., normality) but based on data itself. However, the tools for EDA offer resilient characterizations of statistics and outliers in univariate data as well as anomalous relationships in multivariate data.

Graphical Analysis

EDA stresses on the use of statistical graphics as interfaces between computation and human cognition; these graphics enable users to realize the structure and behavior of data. The most commonly used graphics for EDA, which can be easily stacked on top of other, are (Tukey 1977) density trace, jittered one-dimensional scatterplot, and boxplot (Fig. 1). These are used frequently and jointly with a histogram, as the pictorial intuition one achieves regarding data structure and behavior from just a histogram is prejudiced by user-specified number of classes for its creation. The joint application of such graphics for EDA with a histogram offers superior perception of univariate data structure and behavior compared to one offered by a histogram alone. These three graphics for EDA, unlike a histogram, can easily reveal any “oddities” in a set of data.

A density trace is akin to a histogram although it allows for better realistic perception of the empirical frequency

distribution of data, as its shape is resilient to variation in number of classes. The suitable number of histogram classes can be constrained by creating a jittered one-dimensional scatterplot, which charts data at random locations in a narrow band (typically [0,1] range) perpendicular to data axis. As creation of jittered one-dimensional scatterplot does not rely on classes of data, it delivers supplementary statistics about data (i.e., local densities, structure, behavior, gaps, outliers) that ought to be depicted by a density trace and a histogram. A boxplot portrays descriptive statistics of the empirical frequency distribution of data, and so it is perhaps the most valuable graphics for EDA.

To create a boxplot, data are first arranged from the lowest value to the highest value or the other way around (Fig. 2). The median is defined by counting midway from the lowest value to the highest value, or the other way around, thereby splitting a set of data into two nearly equal subsets. Values of the lower and upper hinges are identified, correspondingly, by counting midway from the lowest value to the median and counting midway from the highest value to the median. The lower hinge, median, and upper hinge split a data set into four nearly equal subsets called quartiles. For a set of data, the first quartile includes values from the lowest to the lower hinge,

Exploratory Data Analysis, Fig. 1 EDA graphics: histogram with density trace (top), jittered one-dimensional scatterplot (middle), and boxplot (bottom)

Exploratory Data Analysis, Fig. 2 Features of a boxplot. Features for values estimated based on the hinge width or the inter-quartile range are labeled in *italics*. Features for observed or measured values at which a univariate data set may be divided into five robust classes are labeled in **bold**. EDA mapping symbols or gray scale colors can be assigned to each class for visualization of data on a graph or a map

the second quartile includes values from the lower hinge to the median, the third quartile includes values from the median to the upper hinge, and the fourth quartile includes values from the upper hinge to the highest. The box, which is defined by the lower and upper hinges, is split often by a line representing the median. The absolute difference of the two hinge values defines the hinge width or inter-quartile range (IQR). A lower inner fence is marked at $1.5 \times$ hinge width and a lower outer fence is marked at $3 \times$ hinge width away from the lower hinge to the lowest value. An upper inner fence is marked at $1.5 \times$ hinge width and an upper outer fence is marked $3 \times$ hinge width away from the upper hinge to the highest value. A lower whisker is marked from the lower hinge and an upper whisker is marked from the upper hinge, toward extreme values within the inner fences. Any value past either the lower or the upper inner fence is regarded as an outlier. Outliers are “mild” if they fall within the inner and outer fences and “far” if they fall beyond either the lower or the upper outer fence. Mild and far outliers are symbolized differently (Fig. 2).

Therefore, a boxplot expresses the five-number summary statistics (lowest value, lower hinge, median, upper hinge, and highest value), and it illustrates the most vital features of a data set, namely (Tukey 1977), (a) central tendency; (b) spread; (c) skewness; (d) lengths of tails; and (e) outliers. As the box embodies roughly two quartiles of a set of data, it implies that $\leq 25\%$ of data may be outlying values; however, outliers radically influence neither the median nor the hinges. Accordingly, the inner fences are not critically influenced by outliers because they are outlined by the hinge width. Thus, a boxplot is a resilient and robust tool for descriptive statistical and graphical analyses of data.

To explore relationships between two variables, say, X and Y , in a set of data, the commonly used graphic for EDA is a scatterplot. In this plot, values of Y , a variable thought to be a response of another variable, are plotted on the y -axis, whereas values of X , a variable suspected to be related to the response variable, are plotted on the x -axis. The relationship of Y to X is revealed by a nonrandom pattern in the plot. Therefore, scatterplots can manifest whether Y is positively or negatively related to X , whether Y is linearly or nonlinearly related to X , and whether or not there are outliers (i.e., pairs of X and Y values that do not conform to the general pattern in a scatterplot). To aid understand higher-level pattern in a set of data with more than two variables, all pairs of scatterplots can be displayed together in scatterplot matrix (Fig. 3); this helps to visualize a correlation coefficient matrix.

For visualization of multivariate data, a typical EDA graphic that can be used is star plot (Chambers et al. 1983). It consists of a series of equiangular spokes, denoted as radii, and every spoke represents a variable. A spoke's length is proportional to the value of a variable for an observation relative to the maximum value of the variable across all

Exploratory Data Analysis, Fig. 3 Example of a scatterplot matrix

observations. A line connects data values per spoke, giving the plot a star-like form and, thus, its name (Fig. 4). Star plots are usually created in a multi-plot format with several stars per page and every star portrays a single observation or sample. A star plot helps to visualize (a) which variables are dominant per observation, (b) presence of clusters of observations, and (c) presence of outliers. However, star plots are useful mainly for multivariate data sets with at most a few hundred points; for larger multivariate data sets, visual analysis of star plots can be cumbersome.

Robust Classification of Univariate Data

A typical research may involve a classification problem. According to a boxplot, a set of univariate data may be split into five robust classes: (1) lowest value, lower whisker; (2) lower whisker, lower hinge; (3) lower hinge, upper hinge; (4) upper hinge, upper whisker; and (5) upper whisker, highest value. For classification of geochemical data for mineral exploration, the first class may be labeled as extremely low background, the second class (comprising $\leq 25\%$ of data set) as low background, the third class (comprising $\leq 50\%$ of data set) as background, the fourth class (comprising $\leq 25\%$ of data set) as high background, and the fifth class as anomaly. Each of these classes can be given suitable symbols (Fig. 2), which can be used to symbolize and visualize the data on a map. Some researchers use the upper inner fence as threshold for distinguishing background values from anomalous values (e.g., Reimann et al. 2005), whereas other research use the upper outer fence as threshold for the same purpose (e.g.,

Exploratory Data Analysis, Fig. 4 Example of multiple star plots for three samples (symbolized by box, circle and triangle) with data for five variables

Yusta et al. 1998). However, because the upper inner fence (i.e., $1.5 \times$ hinge width) or the upper outer fence (i.e., $3 \times$ hinge width) is an estimated value that may not be among the measured values in set of univariate data, outliers past the upper whisker may be regarded as anomalous value. Besides a threshold defined from a boxplot (e.g., upper inner fence or upper whisker), a threshold for distinguishing background from anomalous values can be calculated using EDA statistics as median plus a multiple of median absolute deviation (or MAD). The MAD, which is a measure of data spread, is calculated as median of absolute differences of individual values from their median (Tukey 1977), thus:

$$\text{MAD} = \text{median}[|X_i - \text{median}(X_i)|]$$

where the term $|X_i - \text{median}(X_i)|$ represents absolute deviations of individual values (X_i) from their median (i.e., median (X_i)) in a data set. The MAD is to EDA as the standard deviation is to classical statistics, and so an EDA-calculated threshold of median plus $2 \times$ MAD is equivalent to a threshold calculated as mean plus $2 \times$ standard deviation, which was used traditionally to map geochemical anomalies for mineral exploration (Hawkes and Webb 1962). Certainly, other boxplot- or EDA-derived classes and different class label are possible depending on purpose/scope of research, which dictates what “anomalous values” represent (e.g., anomalous values in exploration geochemistry and in environmental geochemistry are not the same).

In case of univariate data that exhibit presence of several populations, the analysis of only the whole data set is insufficient or even inappropriate for identification of anomalous

values that may be linked with each or some population in the data. It is, thus, crucial to split such data into subsets that represent the different populations present. Univariate data empirical frequency distribution portrayed in a boxplot or in a Q-Q (quantile-quantile) or cumulative probability plot is valuable in graphical analysis to identify gaps or inflection points for splitting data into subsets that represent data populations. Instead, if populations in univariate data are regarded linked to specific geological variables (e.g., rock units), which may also have been logged during the field sampling/observations, then such data may be split into populations according to such variables. Each data population is then subjected to EDA (e.g., boxplot per data subset).

Data Standardization and Transformation

For proper comparison of classes in data populations (e.g., levels of geochemical anomalies in different rock units), a suitable standardization is required. A typical standardization formula from classical statistics is:

$$Z_{ij} = \frac{X_{ij} - \bar{X}_{ij}}{\text{SDEV}_{ij}}$$

where Z_{ij} and X_{ij} represent standardized and original values, respectively, of variable i in population j , and $\bar{X}_{ij}$ and SDEV_{ij} represent mean and standard deviation, respectively, of X_{ij} . As both mean and standard deviation are not resilient to outlying values, data should not be standardized using the above formula. Instead, the following standardization formula from EDA statistics can be used (Yusta et al. 1998).

$$Z_{ij} = \frac{X_{ij} - \text{median}_{ij}}{\text{MAD}_{ij}}.$$

The above standardization formula allows leveling of every population j to one another in a univariate data set, and, thus, classes of different populations in the data set become comparable to one another. The IQR can be used instead of MAD in the above formula. However, using the above formula results in standardized values that can be negative, which cannot be log-transformed if needed. To make all the standardized values positive, say values greater or equal to 1, the following formula may be used (Camizuli and Carranza 2018):

$$z_{ij} = 1 + (Z_{ij} - \min(Z_{ij}))$$

where $\min(Z_{ij})$ is the minimum standardized value. Such EDA-based standardization can be important in the compilation and analysis of, for example, geochemical data pertaining to different map sheets or to different periods of data collection.

Exploratory Analysis of Multivariate Relationships

Any nonrandom relationships among at least two variables revealed from a scatterplot matrix or from star plots can be explored further for detailed understanding of their behaviors by using methods of multivariate data analysis, namely, cluster analysis (Templ et al. 2008) and principal component analysis (Camizuli and Carranza 2018). Cluster analysis can be employed as a tool for EDA to better recognize the multivariate structure and behavior of a set of data. It yields clusters of the data, each cluster consisting of variables that are strongly similar to each other and are strongly dissimilar to the variables in each of the other clusters. Most methods of clustering employ a measure of similarity, which is typically based on distances between values in the data space. Principal component analysis, on the other hand, employs correlations among variables to yield components of data that are uncorrelated. It is useful in determining which variables are redundant in the measure of providing information, and it is useful in recognizing multivariate outliers; it is typically employed as an EDA tool prior to cluster analysis in order to obtain strongly coherent clusters. Details of cluster analysis can be found in the entry on ► [“Clustering and Classification”](#) and those of principal component analysis in the entry on ► [“Principal Component Analysis.”](#)

For exploratory analysis of compositional data (e.g., geochemical data shown in Fig. 3), which are typically affected by the so-called closure problem (see entry on ► [“Compositional Data”](#)), a suitable transformation needs to be applied (see entry on ► [“Compositional Data”](#)) before visualizing multivariate relationships by using EDA graphical tools such as the scatterplot matrix or star plots and before analyzing multivariate relationships through either cluster analysis or principal component analysis.

Concluding Remarks

Exploratory data analysis is widely used in the broad field of geosciences for summarizing and graphically displaying earth

science data collected for a variety of purposes. Exploratory data analysis and confirmatory data analysis are complementary to each other. Exploratory data analysis typically results in information that provide stimulus for further confirmatory data analysis. It is more instructive to employ, first, both exploratory data analysis and, then, confirmatory data analysis than to apply each approach exclusively in order to preclude erroneous interpretation of data.

FAIR guiding principles

Definition

FAIR refers to the four fundamental pillars: 1) findability; 2) accessibility; 3) interoperability; and 4) reusability. The aim is to improve data management and stewardship by empowering computers to find, access, interoperate, and reuse data. FAIR data principles, in brief, are: 1) findable, discoverable with metadata, locatable, and identifiable through a standard identification mechanism; 2) accessible, obtainable, and available all the time; even if the data are restricted, the metadata is open; 3) interoperable, both syntactically explainable and semantically understandable, enabling data exchange and allowing data reuse among researchers, institutions, organizations, and countries; and 4) reusable, adequately described, and shared with the permitted licenses, supported by provenance empowering the broadest reuse possible and minimal tedious integration with other data sources.

Introduction

FAIR data principles are a set of 15 guiding principles aimed at publishing data in a format that enables findability, accessibility, interoperability, and reusability. For better data management and stewardship, data must be findable, accessible,

interoperable, and reusable by human and computer agents. Findable requires that each dataset has a specific global identifier and is combined with accurate, searchable (meta)data. Furthermore, to be accessible, those data and metadata should all be addressed using an accessible, standard protocol; further, they should use a structured, widely understood descriptive language and use popular and widely used frameworks of related vocabulary and ontologies to make the data and metadata interoperable. Finally, excess cross-references and a simple, well-defined procedure for obtaining licensing and provenance data should be richly represented by the data owner to address the data reusability (Wilkinson et al. 2016).

Findable F

“Principle F1: (meta)data are assigned a globally unique and persistent identifier”

Principle F1 specifies that digital resources allocated globally unique and permanent identifiers (i.e., data, metadata, software code, and workflow) to be found and resolved by humans and machines. This principle is an essential principle of FAIR since globally unique and permanent identifiers are core for all the 15 FAIR data principles. Globally unique ensures the identifier corresponds to only one resource in the world unequivocally. Persistence means the condition that even though the digital resource no longer remains or moved, this globally unique and persistent identifier is not ever used anywhere in any sense and perseveres to represent the same digital resource. Practically, this also implies using third-party agencies, such as DataCite that provides a digital object identifier (DOI), to devise an identifier that has assured consistency and is autonomous (Juty et al. 2020).

“Principle F2: data are described with rich metadata”

Principle F2 refers to the capability of locating the digital resource of interest by searching or filtering. Rich metadata should describe the digital resource, the contents of that

digital resource referred to with that descriptor. It is challenging to describe the insufficient richness of these metadata, but the more abundant it is, the more accurately it can be found by both humans and computers in a specific search. Although the other FAIR data principles correspond to certain sets of metadata that must be used, principle F2 perceives it is not possible to discover insufficiently described digital resources. Therefore, this F2 principle inspires data owners to predict the different aspects of a search performed by users, which support the discovery of these digital resources. Moreover, data owners must give general and domain-specific descriptions to permit search engines to locate digital resources (Jacobsen et al. 2020).

“Principle F3: (meta)data clearly and explicitly include the identifier of the data it describes”

Principle F3 stipulates the (meta)data of every digital resource clearly and explicitly includes the identifier of the defined digital resource. For example, in an unambiguous way, the dataset description should specifically include the dataset identifier. This inclusion of the identifier is especially important when the metadata and the digital resource are reserved separately but consistently connected, which is considered by FAIR as a good practice. Besides, by necessitating the metadata to include the identifier of its mentioned digital resource, the identifier can then be effectively used as a search reference for the discovery of its data record (Jacobsen et al. 2020).

“Principle F4: (meta)data are registered or indexed in a searchable resource”

For satisfying this principle, searchable catalogs such as data.gov must register or index the digital resource. The searchable catalog includes the platform from which it is likely to detect the (meta)data identifier, using either the properties of that (meta)data or the digital resource identifier itself (Weigel et al. 2020).

Accessible A

“Principle A1: (meta)data are retrievable by their identifier using a standardized communications protocol”

Principle A1 notes that the retrieval of FAIR data should be mediated without advanced instruments or registered methods of communication. This principle focuses on how this is possible to extract data and metadata from their identifiers. The standardized communication protocol like HTTP and FTP are intended to enforce a predictable method of accessing a digital resource, irrespective of whether open access is given to the content of the digital resource. HTTP (s) and FTP are based on TCP and make it considerably simpler to seek and provide digital resources than other

communications protocols, forming the core of the modern Internet (Jacobsen et al. 2020).

“Principle A1.1: the protocol is open, free, and universally implementable”

The worldwide network protocols, such as HTTP, FTP, and SMTP, are a model for a public protocol, gratis, and globally deployable. Because these worldwide network protocols are well defined and accessible, they minimize the expense of accessing digital resources and permit agents to apply their standards compliance. The free usage of these worldwide network protocols guarantees the digital resource is evenly available to those with less financial resources. It is broadly applicable means the technology is open and not controlled by any country or a specific community (Bailo et al. 2020).

“Principle A1.2: the protocol allows for an authentication and authorization procedure, where necessary”

Principle A in FAIR does not imply “open” and/or “free”; it means that one should determine the exact circumstances under which the data are accessible. Even highly secured and confidential data could also be FAIR. Communication protocols define accessibility in such a manner that they will automatically recognize the credentials and then either perform the requests automatically or alert the user for the requirement. It also prospers practice to allow the data owner to set up a user account to authenticate the owner or contributor of each dataset, and if necessary, to set user-special privileges. These criteria will, however, influence your opinion of where you would store your data (Brewster et al. 2020).

“Principle A2: (meta)data are accessible, even when the data are no longer available”

Digital resources tend to decline or vanish over time because there is a price to retain web presence to data resources. When this occurs, linkages become void, and users will spend hours searching for data that may no longer exist. In practice, maintaining metadata is much cheaper and more convenient than retaining data. Thus, the A2 principle specifies that metadata should be preserved by repositories even though data are no longer available. A2 refers to the issues of registration and indexing listed in F4 (Martone 2014).

Interoperable I

“Principle I1: (meta)data use a formal, accessible, shared, and broadly applicable language for knowledge representation”

Principle I1 means that computers can interpret data despite the need for advanced or functional software, interpreters, or configurations. Usually, interoperability requires that each

computing system at least knows the data integration formats of the other system. To guarantee automated interoperability of digital sources, it is essential to use widely adopted standardized vocabulary, ontology, thesauri with globally specific and permanent identifiers (i.e., principle F1), and well-defined data model structure for representing and structuring (meta) data. A means of defining and structuring the digital sources is the resource description framework (RDF), an extendable knowledge representation model (Vita et al. 2018).

“Principle I2: (meta)data use vocabularies that follow FAIR principles”

Principle I2 utilizes vocabulary to point to approaches, which explicitly describe terms that occur in a specific field. Moreover, the usage of mutual and properly organized terms is an integral portion of FAIR. Furthermore, constructing community standards require structured terminology containing fine-grained knowledge specifications such as data structures and ontologies and structured thesauri. The vocabulary used to describe (meta)data, though, must be searchable, reachable, interoperable, and reusable by itself so that people, as well as computers, can understand the context of the metadata terms used. Furthermore, computers should effectively differentiate the used vocabulary terms in RDF, the language for knowledge representation. Therefore, principle F2 demands that the vocabulary used must adhere to FAIR data principles (Lamprecht et al. 2020).

“Principle I3: (meta)data include qualified references to other (meta)data”

The objective of Principle I3 is to establish as many concrete ties as necessary across (meta)data in (meta)data repositories to improve contextual data knowledge. A qualified reference is a cross-reference defining its purpose. To be quite specific, if one dataset depends on another dataset, you must determine if more datasets are required to fulfill the whole data or if supplementary content is deposited in diverse datasets. In particular, the scientific ties between datasets must be specified by dataset owners. Furthermore, all datasets, and their globally unique and persistent identifiers, must be referenced (Lamprecht et al. 2020).

Reusable R

“Principle R1: (meta)data are richly described with a plurality of accurate and relevant attributes”

When many annotation tags are assigned to the data, it would be much faster and easier to discover and reuse data. Principle R1 is same as F2, but R1 depends on a user’s (machine or human) capacity to determine if the data in a specific context is useful. To make this determination, the data owner should

include not only metadata that facilitates exploration but also metadata that richly represents the context under which the data was created. These activities could involve the research method, the producer, and the model of the instrument or device that provided the data, the organisms that used the drug regime, and any other source of data. Moreover, R1 declares that the owner of data does not intend to anticipate the identity and desires of the data user. To suggest that the metadata creator should be as lavish as possible in supplying metadata, even though with details that might seem unrelated, we used the phrase “plurality” (Jacobsen et al. 2020).

“Principle R1.1: (meta)data are released with a clear and accessible data usage license”

Principle R1.1 is a matter of legal interoperability. What rights of access apply to data? These rights of access must be explicitly defined. Uncertainties can dramatically impact the reuse of your data by companies struggling to conform to licensing restrictions. In addition, the clarity of licensing status would become more substantial with digital searches requiring more licensing criteria. Without exception, digital resources and their (meta)data must always contain a license defining the state of its use. Moreover, it must be apparent to humans and computers the circumstances under which the digital resources will be used. Furthermore, the license specified must be as open as possible to enable reuse, therefore licenses widely used, such as MIT and Creative Commons, can be connected to your digital resource (Labastida and Margoni 2020).

“Principle R1.2: (meta)data are associated with detailed provenance”

Principle R1.2 indicates that a precise history of provenance should be known in order to reuse the digital resource. Furthermore, provenance addresses detailed information covers factors like: 1) How the digital resource was created? 2) Why it was produced? 3) Under what circumstances, based on which original data or digital resource of origin and what grant is used? 4) Who manages the data that should be attributed? and 5) What are the modifications and cleaning methods used since creation? Both humans and computers need provenance information and data manipulation techniques to determine whether a digital resource meets their requirements for intended reuse (Jauer and Deserno 2020).

“Principle R1.3: (meta)data meet domain-relevant community standards”

Principle R1.3 declares that (meta)data ought to comply with community standards or community best practices if they exist. Moreover, minimal information standards (e.g., MIAME, MIAPE, and ISO 19115-2) have been established by many organizational communities, defining the minimum

collection of metadata items needed to determine data processing and the data extraction standard to promote reusability. Furthermore, the FAIR data demand to at least conform to these standards; other community criteria are less standardized, but the purpose of FAIRness is to present (meta)data in a way that improves its reusability for the community. Eventually, these standards are a decent start point, considering that real reusability would usually involve additional richer metadata (Jacobsen et al. 2020).

Summary and Conclusions

We have defined the FAIR data principles and explained the enclosed 15 FAIR data principles. Toward better data management and stewardship, digital resources ought to be findable, accessible, interoperable, and reusable by human and machine. Furthermore, several aspects are explained to help improve data management and stewardship for digital resources.

Finally, scientific communities are confronted with several challenges such as lack of metadata standard, struggle to locate needed datasets, ruinous metadata authoring process, and longtime spent on data curation. Therefore, the solution to rectify these issues is to have satisfying data management and stewardship that relies on adopting FAIR data principles.

Fast Fourier Transform

Frits Agterberg

Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

The Fast Fourier transform (FFT) is an algorithm that computes the discrete Fourier transform of a 1-dimensional sequence or a 2- or 3-dimensional array. In general, Fourier analysis converts a signal from its original domain (usually time or space) to a representation in the frequency domain (and vice versa). The discrete Fourier transform of complex numbers $x_0, \dots, x_{N-1}$ can be written as:

$$X_k = \sum_{n=0}^{N-1} x_n e^{-2\pi i k n / N} \quad k = 0, 1, \dots, N-1$$

where $e^{2\pi i / N}$ is the primitive N th root of 1. In terms of big O notation, direct evaluation of this definition requires $O(N^2)$ operations but the FFT requires only $O(N \log_2 N)$ operations. Other formulations and algorithms of the FFT can be found in Press et al. (2007). The preceding definition applies to 1-dimensional series. Savings in computing time are even greater in 2- and 3-dimensional applications of the FFT.

Introduction

The most commonly used FFT algorithm is the one devised by Cooley and Tukey (1965). Historically it is of interest that Heideman et al. (1984) discovered much later that the earliest version of the FFT can be traced to unpublished work by Gauss in 1805 who used it in an unpublished manuscript for interpolation to describe the orbits of two asteroids. A brief history of early FFT inventions and applications can be found in Cooley et al. (1967).

Many features in the Earth's crust tend to be periodic in that they repeat themselves at more or less the same intervals. Examples are anticlines and synclines as well as fault systems. In these situations, harmonic trend analysis can produce much better results than other 2-D interpolation techniques including polynomial trend surface analysis. The 2-D power spectrum and autocorrelation function are important tools even when there are no spatial periodicities. A 2-dimensional example of harmonic trend surface analysis using the Cooley-Tukey algorithm will be given later in this entry. The relationship between harmonic analysis and other 2-D

geostatistical methods also will be considered. The 2-D theory of FFT-based 2-D harmonic analysis can be summarized as follows (cf. Agterberg 1974, 2014).

The inverse Fourier transform $A(p, q)$ of a 2-D array of gridded $(m \times n)$ data, $X_A(i, j)$ satisfies:

$$A(p, q) = \frac{1}{mn} \sum_{i=0}^{m-1} \sum_{j=0}^{n-1} X_A(i, j) \cdot \exp \left[-2\pi I \left(\frac{ip}{m} + \frac{jq}{n} \right) \right]$$

where $I = \sqrt{-1}$.

Consequently, $X_A(i, j) = \frac{1}{mn} \sum_{p=0}^{m-1} \sum_{q=0}^{n-1} A(p, q) \cdot \exp \left[-2\pi I \left(\frac{ip}{m} + \frac{jq}{n} \right) \right]$.

Without loss of generality, it can be assumed that $\bar{X}_A$ is zero. Any value $A(p, q)$ consists of a real part $\text{Re}(A_{p,q})$ and an imaginary part $\text{Im}(A_{p,q})$. Any wave can be represented by the continuous function:

$$X(p, q; u, v) = \text{Re}(A_{p,q}) \cos \left[2\pi \left(\frac{ip}{m} + \frac{jq}{n} \right) \right] - \text{Im}(A_{p,q}) \sin \left[2\pi \left(\frac{ip}{m} + \frac{jq}{n} \right) \right],$$

where u and v are geographical coordinates. The square of amplitude is given by:

$P(p, q) = \text{Re}^2(A_{p,q}) + \text{Im}^2(A_{p,q})$ and the 2-D autocovariance satisfies:

$$C(r, s) = \sum_{p=0}^{m-1} \sum_{q=0}^{n-1} P(p, q) \cdot \exp \left[2\pi I \left(\frac{ip}{m} + \frac{jq}{n} \right) \right].$$

The $X(p, q; u, v)$ functions for a block of values (p, q) then form a so-called harmonic trend surface with: $Y(u, v) = \sum_p \sum_q X(p, q; u, v)$.

Application to Drill-Hole Data from the Whalesback Copper Deposit

Figure 1 shows a longitudinal cross-section of the Whalesback copper deposit, Newfoundland. It contains the intersection points of 188 underground drill-holes with the central part of the ore zone. The average copper value was calculated for each hole over the width of the orebody. This

Fast Fourier Transform,

Fig. 2 Two-dimensional autocorrelation function for data from Table 1, Whalesback copper deposit. (Source: Agterberg 1974, Fig. 61)

Fast Fourier Transform,

Fig. 3 Part of 2-dimensional power spectrum for data in Table 1; sharply defined peak reflects zoning of copper percent-foot values shown in Fig. 1. (Source: Agterberg 1974, Fig. 77)

value was multiplied by horizontal width yielding so-called percent-foot values contoured by mining staff. The central part of this diagram shows a relatively rich copper zone that dips about 45° downward to the west.

For the FFT application, the array of Table 1, which is based on Fig. 1, was enlarged to size (32 × 32). The resulting

2-D autocorrelation function and power spectrum are shown in Figs. 2 and 3, both of which demonstrate the strong zoning in this ore deposit. The central copper zone is flanked by two elongated minima and at about 460 ft. from it there occur two other relatively copper-rich zones, although their maxima are not as high as that for the central zone. The following

Fast Fourier Transform,

Fig. 4 Harmonic analysis of irregularly spaced data (after Agterberg 1974). Intersection points of 20 exploratory boreholes from topographic surface with ore-zone shown in (b). Two-dimensional sine-waves were fitted to 20 values by least squares method; percentage explained sum of squares for each fitted wave is shown in (a) with period scale in feet. Wave for value 44 on peak in (a) is shown by straight-line contours in (b), and also in cross-section for horizontal line ($V = 10,600$) near topographic surface in (c). (Source: Agterberg 1974, Fig. 78)

experiment illustrates further that harmonic analysis can be an excellent exploration tool in situations of this type.

Development of the Whalesback copper deposit was performed at two different stages. Before the deposit was mined, it was explored by drilling relatively few bore-holes downward from the surface of the Earth. Statistical analysis applied subsequently to these original data is shown in Fig. 4.

Copper percent-foot values from these surface boreholes are shown in Fig. 4b. There were only 20 exploration values, which are irregularly distributed. The question can be asked of how the pattern of Fig. 1, which is based on 188 more precise underground drill-holes, which are more evenly spaced and were sampled in much more detail as well, could have been predicted from these 20 values. This kind of

problem is analogous to that of constructing a topographical contour map of a mountain chain when only a few elevations would be provided for interpolation. Simple polynomial trend surface analysis applied to the 20 development values produces patterns that show no resemblance to the pattern of Fig. 1. In general, trend surface results can be evaluated by using squared multiple correlation coefficients R^2 that provide a convenient measure to assess degree of fit of a trend surface. In its application to the 20 values of Fig. 4, both the linear ($R^2 = 0.16$) and quadratic ($R^2 = 0.32$) fits were found to be not statistically significant.

On the other hand, Agterberg (1974) fitted the function $X(p, q; u, v)$ (see previous section) by least squares to estimate the coefficients $b_1 = \text{Re}(A_{p,q})$ and $b_2 = \text{Im}(A_{p,q})$ for many possible directions of axes and periods for the waves. Ideally, a least-squares model should have been used by which the four parameters (direction of axis, period, amplitude, and phase) are estimated simultaneously but then a nonlinear model should have been developed and applied. The linear model can only be used when p/m and q/n are assumed to be known. For each separate sine wave, R^2 was plotted as a percentage value in Fig. 4a. The result can be regarded as a 2-D power spectrum for irregularly spaced data. Since three coefficients were fitted for each sine wave (including the constant term that is related to the mean value), its R^2 value could be converted into an F -value at the upper tail of a theoretical F -distribution with 3 and 17 degrees of freedom. The $F_{0.95}$ - and $F_{0.99}$ -values correspond to 27% and 37% values for R^2 and these were contoured. There are two contoured peaks in Fig. 4a and one of these corresponds to the peak in Fig. 1. The contour map of the sine-wave whose amplitude falls on the well-developed peak of Fig. 4a is shown in Fig. 4b, and its profile for a line along the surface ($V = 10,600$) in Fig. 4c. The 20 original observations were projected onto Fig. 4c along lines parallel to the contours. Obviously, the contours in Fig. 4b are an oversimplification of those shown in Fig. 1 but existence of zones with alternately high and low copper could already have been correctly predicted from as few as 20 bore-holes drilled from the surface.

Summary and Conclusions

The Fast Fourier transform (FFT) is an algorithm that computes the discrete Fourier transform of a sequence or a 2- or 3-dimensional array. It can be used to convert a signal from its original domain (usually time or space) to a representation in the frequency domain (and vice versa). In this entry, the 2-dimensional version of the Cooley-Tukey algorithm was used to illustrate that in mathematical geoscience this approach is particularly useful to analyze 2-dimensional map patterns that are spatially repetitive in nature. Copper

analyses from drill-cores from the Whalesback Mine in Newfoundland were taken for example. The FFT method was used to obtain 2-dimensional autocorrelation function and power spectrum for the spatial distribution of copper in this copper deposit. It was also shown that a relatively small number of bore-holes drilled from the surface during early exploration would already have yielded the intrinsic pattern of copper mineralization obtained by harmonic analysis of the later underground mining data.

Fast Wavelet Transform

Indu Solomon and Uttam Kumar

Spatial Computing Laboratory, Center for Data Sciences,
International Institute of Information Technology Bangalore
(IIITB), Bangalore, Karnataka, India

Definition

A signal is said to be stationary if its frequency content is invariant with time. These signals can be analyzed with techniques such as Fourier transform. Nonstationary signals, on the other hand, are those whose frequency content changes with time. The nonstationary signals are analyzed using wavelet transform as it helps to decompose the complicated

signal into simpler components. Wavelet transform is constituted by wavelets that are small oscillations or wave-like signals. Scale and location are two main properties of wavelets. Scale of the wavelet defines the stretch or squeeze of the wavelet, and location property gives the time or space positioning. The faster version of wavelet transform known as Fast wavelet transform was introduced by Mallat (1989).

Introduction

A brief history of wavelet transform (Chun-Lin 2010) needs a mention here. Haar wavelet was proposed in 1909 by the mathematician Alfrd Haar, but the concept of wavelets did not exist at that time. Later, wavelet was proposed in 1981 by the geophysicist Jean Morlet. Eventually, the term wavelet was introduced by Morlet and Alex Grossman in 1984. The second orthogonal wavelet after Haar wavelet was introduced in 1985 by mathematician Yves Meyer and is called Meyer wavelet. Multiresolution analysis concept was introduced by Mallat and Meyer. Compact support orthogonal wavelet was introduced by Daubechies. Fast wavelet transform was proposed in 1989 by Mallat, and later on various applications of wavelet transform in the field of signal processing were identified.

A wavelet is a mathematical function which is used to decompose a given signal into different scale components. The wavelets are scaled and translated copies of fast decaying waveform called mother wavelet. The scaled and translated copies are called daughter wavelets. There are numerous applications for wavelet transforms in the field of signal processing viz. data compression, signal denoising, image compression, signal analysis, etc. Wavelet transforms are widely used in geoscience applications as well as for example, spatial analysis tool for modeling complex multivariate geographic relationships. Wavelets are also used in spatial statistics and spatial analysis of landscape patterns.

Wavelet Transform

The continuous wavelet transform (CWT) is defined as follows:

$$\Psi_x^\psi(\tau, s) = \frac{1}{\sqrt{|s|}} \int x(t) \psi^*\left(\frac{t-\tau}{s}\right) dt \quad (1)$$

The transformed signal is a function of two variables τ and s , where τ represents translation and s represents the scale. The transforming function $\psi(t)$ with which the signal is convoluted is called the mother wavelet. The mother wavelet is the main function from which other windowing functions called daughter wavelets are generated. The term translation

refers to the location of the window function, and translation captures the time information of the signal (Polikar 1996). The scale parameter is inverse of the frequency of wavelet. Low scales of wavelet give very fine details, and high scales give lesser details. The scale $s > 1$ elongates the signal and $s < 1$ compresses the signal. The wavelet function is convoluted with the given signal by translating through the time axis at multiple scales and the transformed values are stored for further processing. Unlike other transformations, the main advantage of wavelet transform is that it can simultaneously extract spectral and temporal information. Multiresolution analysis is used to analyze a signal at different frequencies with different resolutions. Multiresolution analysis is useful in giving good frequency resolution and poor time resolution at low frequencies (Morehart et al. 1999), and good time resolution and poor frequency resolution at high frequencies. This approach is helpful for analyzing most naturally occurring signals, as they have slow varying low-frequency components and fast varying high-frequency components. Multiresolution interpretation diagram for wavelet transforms is shown in Fig. 1. Even though the height and width of each box is different in Fig. 1, their area is same. At low frequencies, the height of the boxes are shorter and width are longer representing better frequency resolution and poor time resolution.

CWT Versus DWT

Continuous wavelet transform (CWT) decomposes a signal into wavelets over the whole real axis and hence over infinite

Fast Wavelet Transform, Fig. 1 Time and frequency resolution interpretation

scales and locations while the discrete wavelet transform (DWT) samples the signal over a range of integers and uses a finite set of wavelets. Since CWT is computationally intensive, DWT is more suited for real-time applications. The Mallat algorithm for DWT is known as fast wavelet transform. It is known as a two-channel subband coder using conjugate quadrature filters or quadrature mirror filters (QMFs).

Fast Wavelet Transform (FWT)

In case of FWT, the signal is passed through a set of filters to extract the details of the signal. Low-pass filters and high-pass filters are used to extract low-frequency and high-frequency information, respectively. DWT decomposes the signal into coarse approximation and fine detail information. The decomposition halves the time resolution and doubles the frequency resolution and can be repeated multiple times. The process is called subband coding which reduces the uncertainty in frequency. Figure 2 shows an example of subband decomposition of an image. The decomposition algorithm starts with signal S . S is decomposed into approximation coefficients A_1 and detail coefficient D_1 , and then A_1 is further decomposed into approximation A_2 and detail D_2 . The inverse transform starts with approximation coefficients A_n , detail coefficients D_n , and computes A_{n-1} , and so on. FWT is a power-of-two algorithm. Each successive decomposition of the FWT operates on a vector which is half the size of the previous operation. This is achieved by decimation in time of the multiresolution analysis. Lossless and lossy compression are

Fast Wavelet Transform, Fig. 2 Subband decomposition of an image

two main applications of FWT in image compression applications (Boyer 1995). FWT was introduced to remove the border effects caused in DWT. FWT algorithm is suitable for computationally intense geospatial applications too.

Wavelet Families

There are various wavelet families and the selection of best family is based on the shape of the signal to be processed. Few of the wavelet families are Haar, Daubechies, Biorthogonal, Coiflets, Morlet, Mexican Hat, and Meyer. Figure 3 shows examples of the shape of wavelet function for selected wavelet families.

DWT: Case Studies in Geospatial Applications

There are many geospatial domains in which wavelet transforms are extensively used, namely tree detection (Stupariu et al. 2020), ecology (Dale and Mah 1998), crop yield estimation in agriculture, cloud detection, spatial traffic analysis, soil variation study, and so on. This section will discuss some important applications of DWT in geospatial domain.

Classification of Hyperspectral Images Based on 3D: DWT

Hyperspectral image consists of a large number of spectral bands of narrow bandwidth and the number of spectral bands (channels) often depends on the sensor. Hyperspectral images are useful in a wide variety of applications including geology, mining, agriculture, mineralogy, environment, surveillance, and so on. Wavelet transforms are very useful for non-stationary signals and can extract location (spatial) and frequency (spectral) information from the signals. 3D discrete wavelet transformation is generally used for extracting the spatial and spectral features from the hyperspectral images and these extracted features are used as input to a trained

Fast Wavelet Transform, Fig. 3 Example – wavelet families

classifier for classification (Anand et al. 2021). Three-dimensional wavelet transform was implemented with the help of three-stage 1D wavelet transform using Haar, Fejér-Korovkin, and Coiflet wavelet. First step of the algorithm uses principal component analysis (PCA) for reducing the dimensionality of the data to get compact representation. The second step is to apply 1D - DWT to the rows of the compact data and feed the outputs of 1D - DWT along with the columns to generate the wavelet transform in different image dimensions. This creates four subbands with spatial and spectral features that are then fed to the classifier. The classification experiments were performed on the Salinas and Indian Pines hyperspectral dataset.

Remotely Sensed Image Data Fusion: A Wavelet Transform Approach for Urban Analysis

There are several existing techniques for fusing panchromatic and multispectral data to obtain high spatial and spectral resolution images. Compared to the traditional techniques, multiresolution wavelet decomposition based techniques give a better trade-off between spatial and spectral information (Fanelli et al. 2001). Prerequisite for fusion of two images is that both the images must be of the same spatial resolution. If this is not the case, either we upsample or downsample one of the images to match the resolution. Upsampling is preferred over downsampling because downsampling a high resolution image takes away important details from the image. In Fanelli et al. (2001), bicubic resampling technique was used for resampling the IKONOS multispectral images to the resolution of IKONOS panchromatic image. Brovey, HSV, and PCA transformations are a few classical techniques used in literature for fusion of satellite images. These classical techniques are simple and easy to implement, but they distort the spectral (thematic) details in the fused images.

Multiresolution wavelet decomposition based fusion technique such as Dyadic Wavelet Substitution (DWS) solves the issues of classical fusion techniques. DWS is as summarized below:

- Select the wavelet basis family and the required wavelet decomposition level.
- Apply histogram matching between panchromatic image and selected multispectral band.
- Perform wavelet decomposition of panchromatic image and selected multispectral band to obtain low-frequency approximation and high-frequency detail images.
- Replace the low frequency approximation image of panchromatic wavelet decomposition with the high spectral content (low-frequency) approximation image of the multispectral data.
- Perform inverse wavelet decomposition to obtain high spectral and spatial content multispectral fused images.

The abovementioned wavelet decomposition based fusion technique is very simple and effective in retaining the spectral details compared to classical fusion techniques.

Evaluation of Spatiotemporal Characteristics of Precipitation Using Discrete Maximal Overlap Wavelet Transform and Spatial Clustering Tools

The monthly precipitation characteristics of 30 stations in southeastern United States during the time period of 1968–2018 were studied in a recent research (Roushangar et al. 2021) where maximal overlap discrete wavelet transform (MODWT) was used for data preprocessing. Daubechies (db) wavelet family was selected for processing and the data were decomposed into various subbands using MODWT. Finally, K-means clustering was used for grouping the data.

MODWT is a modified version of DWT. It can perform a multiresolution analysis of the time series signal. MODWT projects the time series data onto a collection of non-orthogonal basis wavelet functions. For a time series P with N samples, MODWT is given by

$$P = \sum_{j=1}^N W_j + V_N \quad (2)$$

where W_j is the wavelet coefficients, V_N is scaling coefficients, and N is the decomposition level. The output of MODWT was fed as input to the clustering model. Energy E values for each of the wavelet subband for each wavelet and scaling factor were calculated from the precipitation values.

The MODWT-K-means framework was used for investigating spatiotemporal analysis of precipitation. MODWT was used to extract multiresolution features of nonstationary data, and K-means could locate spatially identical clusters on wavelet-transformed feature space.

Summary and Conclusion

Wavelet transforms are very useful for analyzing non-stationary or time series signals. They are capable of analyzing a signal at different scales and different times known as multiresolution analysis. There are different varieties of wavelet families with different basis functions, and we can select a suitable wavelet family depending on the signal to be analyzed. Wavelet transforms are extensively used for signal-processing and image-processing applications. FWTs are capable of removing the border artifacts caused due to DWT and are extensively used in image compression applications. Wavelet transforms are robust and useful for geospatial

applications as well. Few case studies of geospatial applications which used wavelet transforms were discussed in this chapter.

Favorability Analysis

Guocheng Pan

Hanking Industrial Group Limited, Shenyang, Liaoning, China

Definition

Mineral target selection has been an important step for search of mineral deposits in mineral exploration. Significant progress has been made so far in development of mathematical

techniques and estimation methodologies for mineral target selection. Integration of multiple data sets, either by experts or statistical methods, has become a common practice in estimation of mineral potentials. Geoscience map patterns are commonly used as primary inputs for decision-making on mineral target selection. Favorability analysis as a broadly adopted methodology for data integration and target selection can be effectively applied by using modern GIS technologies. The outputs of the analysis are prognostic maps that indicate where hidden ore bodies or mineralized objects may occur. Favorability analysis is a whole class of mathematical tools that are capable of quantifying and integrating diverse geoscience information for mineral potential mapping. This chapter will introduce the concepts of geoscience information synthesis and discuss rudimentary favorability modeling techniques, including characteristic analysis and canonical favorability analysis.

Introduction

The activities of mineral exploration have been motivated chiefly by economic and social pursuits (Pan and Harris 2000). Constantly growing economic and social demands require greater amounts of raw material, including non-renewable mineral commodities. The conduct of mineral resource exploration is predicated upon the economic rent expected from the discovery of new deposits. An increase in the price of a mineral product, which is equivalent to the sum of the marginal rent and marginal extraction cost, indicates that the mineral resource has become scarce. A basic perspective of both geologists and economists is that mineral resources are scarce materials in the crust as they occupy only an insignificant portion of crustal material.

Any major ore deposit may be regarded in principle as an anomalous or rare phenomenon commonly characterized by one or more geological, geochemical, and geophysical features. Consequently, signatures of significant endogenic mineralization are anomalous and exceptional geologic settings created by earth processes (Pan 2010, 2018). In particular, the formation of a giant deposit is an extremely rare event created by an exceptional combination of earth processes. Rareness of the giant deposits is reflected in both spatial and temporal dimensions. Significant concentrations of a metal usually have a strong affinity or correlation with special geologic formations and epochs, as well as metallogenic environments. The genesis of giant deposits may be controlled by special regularities that differ from those controlling the formation of medium and small-size deposits of the same composition.

Simply stated, mineral exploration is the process of searching for undiscovered mineral deposits. While such a statement is correct, it belies the complexity and diversity of tasks and decisions that constitute modern exploration. In

private-enterprise economies, mineral exploration is both a process of scientific detection and a business investment. To be successful on a continuing basis, exploration must find not just an ore deposit, but a deposit that can be developed technically and produced economically. This compounds difficulties and risk, because such deposits generally constitute only a small percentage of those deposits that occur in a region. Nevertheless, successful discovery of such a deposit initiates profitable economic activity that may endure for many years, providing cash flow for future exploration and development ventures.

Exploration bears a high risk. The risk occurs in the exploration investment that may not lead to an economic discovery. Hence, the key for a successful exploration program is to minimize the uncertainty of target selection. Reduction of the uncertainty of drilling targets helps increase the chance of new discoveries and on average shorten the cycle of a successful exploration process. This can be achieved by full use of available data by means of mathematical integration technologies, such as Favorability Analysis.

Basic Concepts

A major task in modern exploration programs aims at the delineation of targets for the search of blind ore bodies as mineral deposits outcropped or near the earth surface are quickly depleting. Due to the advent of advanced information technologies, various multivariate techniques have been introduced to interpret and integrate complex and multiple geoscience maps for target selection. Favorability analysis is one of the most powerful tools for such a task (Pan and Harris 1992a; Pan 1993a). The idea of favorability analysis is to construct a linear combination of a set of selected geoscience variables relevant to the mineral deposit or occurrence of interest.

Classification of Spatial Variables

Mineralization is always associated with some special physical and chemical properties within a favorable mineralization environment. For example, an epithermal gold occurrence is often relevant to a heat source or an event of igneous intrusion or volcanic eruptions, which provided heat and fluids necessary for metal movement and concentration. The enriching process of a metal is generally related to multiple geological, geochemical, and geophysical processes in the spatial domain that contains the mineralization. This most often involves structural movements, faulting, and hydrothermal alterations as signatures of metal concentration.

Descriptors of mineral deposit or occurrence can be direct or indirect variables, which can take continuous or discrete (including categorical) values. It is customary that continuously valued attributes like magnetic measurements are considered as quantitative variables, while discrete or categorical attributes such as rock type are treated as qualitative variables. Soil geochemical measurements are typically quantitative, while presence or absence of mineral occurrence is regarded as qualitative binary data. Most quantitative or qualitative variables that define unique components of mineralization belongs the category of direct descriptor, such as gold grade of a gold deposit, copper grade in a porphyry copper deposit, and presence of mineral occurrence.

Each geoscience attribute can be classified as either “target” variable or “explanatory” variable (Pan and Harris 1992a; Pan 1993a). The attributes that provide direct evidence on the mineral occurrence of interest are referred to as target variables, such as mineral resource descriptors, metal grades, and key hydrothermal alteration assemblage. These features are usually known only in the best explored parts of the study region and are unevaluated in the rest of the region. Target variables characterize the major objective of a study and serve as identification criteria for target selection.

The attributes that contain indirect information on the mineral occurrence of interest are referred to as explanatory variables, which consist of various geoscience measurements, such as chemical and physical descriptors of favorable geological objects. Explanatory variables are generally observable throughout the entire study region by means of conventional sensing and sampling technologies. Stream sediment geochemical measurements, gravity observations, and intensity of magnetic flux are a few examples of explanatory variables.

Geophysical surveys generate a broad range of physical property measurements, including magnetic intensity, gravity density, IP conductivity, electro-magnetic resistivity, etc. Most of these are usually treated as explanatory variables that provide indirect information. Geochemical prospecting provides information on both explanatory and target variables. Anomalous gold assays from rock samples exhibit direct evidence on the gold mineralization, which can be treated as target variables. Concentrates of associated elements, such as As and Hg, reveal indirect signatures, which are used as explanatory variables. Table 1 contains an example of the two types of geological variable identified for an epithermal gold-silver district.

Lithology carries both target and explanatory information. For example, presence of well-defined mineralized host rocks on a map area can be treated as a useful target variable that provides firm or direct evidence for the presence of mineralization, whereas post-mineralization units laying over the host rock may be viewed as explanatory characteristics.

Favorability Analysis, Table 1 Example of explanatory and target variables

Variable Class	Label	Descriptions of the Information Fields	Data Type
Explanatory Variables	Z1	Preprocessed geochemical fields	Continuous
	Z2	Synthesized structural fields	Categorical
	Z3	Band-pass gravity fields	Continuous
	Z4	Band-pass magnetic fields	Continuous
	Z5	Ratio of EM fields	Continuous
	Z6	Correlated geophysical fields	Continuous
	Z7	Host rocks of gold-silver deposits	Ternary
	Z8	Depth estimates to hidden intrusives	Continuous
Target Variables	Y1	Hydrothermal alteration assemblages	Binary
	Y2	Mineralized Tertiary intrusives	Binary
	Y3	Gold-silver mines or occurrences	Discrete

Similarly, local ore-controlling shear zones are usually recognized as powerful spatial target variables, but regional contemporary structures like faulting and folding may be employed as explanatory variables.

Quantification of Geoscience Maps

Geological bodies like ore deposits, intrusive, and fault zones are typical 3D objects. Most geoscience attributes are considered as spatial random variables, each carrying spatial location and geologic typicality in a 3D space. For example, a magnetic observation is viewed as a random variable realization at the sampled location and the measurement physically exhibits magnetic intensity of geological objects at and around that location. However, most data integration techniques for target selection are carried out in 2D space due to restriction of information acquisition in the third dimension (like drilling). In practice, data integration is usually performed on geoscience maps or “layers,” each of which contains a geoscience attribute of interest. Combination of these multilayers is facilitated greatly with assistance of modern GIS technologies.

Typical geoscience layers are geological, geochemical, and geophysical maps. Geological maps include rock formations, structures, alterations, and mineral occurrences. Geochemical prospecting generates maps of rock samples, stream sediment, and soil samples. Geophysical surveys create various maps of physical properties, such as gravity, magnetic flux, and EM fields. Spatial target variables provide direct and firm evidence for mineral anomalies or deposits on a map, whereas spatial explanatory variables are expressive of indirect evidence or relevant signatures for mineralization.

Spatial variables are usually observed or sampled on a map or study region which is divided into many equal-sized cells, also referred to as inter-grid cells (see Fig. 1). Each cell

on the map is considered as a sampling point (1D) or area (2D) or block (3D), where information on the value and location is recorded for each spatial variable involved in the analysis. In many cases, geoscience variables are not sampled in a regular grid and they must be preprocessed into cell-based observations. For instance, a stream sediment sampling generally follows stream basin patterns instead of a regular grid. The sediment anomalies should then be restored to their sources and interpolated into a regular grid prior to further modeling.

It is often that original maps are preprocessed before being used in data integration. For instance, magnetic and gravity maps preprocessed for noise removal and signal enhancement prior to integration are more informative in revealing anomalous basement structures and heat sources at depth. Geochemical maps after removal of regional background by trend analysis reveal subtle anomalous signatures for the mineralization of interest.

A fundamental principle in quantitative target evaluation is to assume that the data indeed provide reasonable descriptions on the nature of mineralization and their variability in space. The descriptions can be either quantitative or qualitative with the reference of evidential nature of spatial mineral distributions. The accuracy of target prediction largely depends on the amount of information contained in the data sets and captured in quantitative modeling.

Prior to data integration, the map variables must be assigned with values in each cell. The value assignment to the j^{th} geoscience variable at cell i (z_{ij}) is relevant of both science and art. Appropriate assignment requires scientific knowledge and ad hoc judgment as well. Geophysical and geochemical data are usually continuous and the cells can be assigned with actual measurements or processed values. Most geological features on a map are discrete or categorical and their cells are usually assigned with qualitative values in binary and ternary forms (Table 1).

Favorability Analysis,

Fig. 1 Inter-grid based favorability analysis (CFM) for mineral potential mapping

Control Area and Statistical Analogy

Most favorability analysis for mineral potential mapping is constructed on some pre-selected well-explored subregions on a map, which are collectively called the Control Area (Fig. 1). The favorability model established in the control area can then be extrapolated into unknown regions for favorability estimation using the principle of analogy. A control area can be one map region or a collection of several disconnected subregions. Target variables are usually known or observable within the control areas, whereas explanatory variables are generally available or measurable in the entire study map. An area that qualifies as control area must satisfy the following conditions:

- The area must be well-explored and all target variables and explanatory variables involved can be recorded or observed.
- The mineralization style of interest in the area is typical and representative of the entire study region.
- The characteristics of association between target and explanatory variables established in the control area are representative or roughly homogeneous throughout the entire study region.
- Major deterministic conditions for ore-controlling geological formations and structures in the control area are relatively uniform in other areas of the study region.

Data integration using the control area assumes the fundamental principle of statistical analogy, which implies that similar geological environments should have similar mineral occurrences. In the same token, it assumes that similar mineral deposits occur in similar geological and tectonic environments. Clearly, this assumption is conceptually reasonable but practically difficult to verify.

In general, the principle of analogy is used in a statistical sense for some given conditions. For example, within the study area, similar controlling geological factors are considered as “necessary conditions” for the same type of deposit to occur. This relaxed assumption makes it possible to predict mineral targets based on the information collected from known deposits within the same study area.

Quality of the Favorability estimates are heavily reflective of the “quality” of control areas, that is, how good of a geological analogue the control area is of the unexplored region. When analogue and desired mineral potential estimate is for geological conditions similar to those that induced the exploration of control area, the estimates produced by a favorability model established on the control area may be unbiased and reliable. However, when geological references for the estimates differ or when the control area is not a good geologic analogue, favorability estimates tend to be biased and even totally meaningless (Pan 2018).

Characteristic Analysis

Characteristic analysis (CA), proposed by Botbol (1978), was demonstrated as a tool for quantitatively describing how typical each of a number of geological characteristics, such as mineralogy, geochemistry, and geophysics, is of a set of mineral deposits (Harris 1984; Pan and Harris 1992b). This statistical technique was later used as a tool for target selection in mineral exploration (McCammon et al. 1983). CA is perhaps the most primitive form of favorability analysis.

Like most other statistical models in mineral exploration, characteristic analysis is primarily constructed on observations or measurements taken in and around known ore deposits. Use of the model has been predicated upon the assumption that favorability to the mineral potential of a

region is a positive function of the similarity of its characteristics with those of the known deposits.

Let $\mathbf{Z} = (z_{ij})$ denote the matrix containing n observations on m characteristics (explanatory variables), where z_{ij} is either binary or ternary. In the binary form, $z_{ij} = 1$ if characteristic j exists in cell i and 0 otherwise. In the ternary form $z_{ij} = 1$ if its presence is favorable; $z_{ij} = -1$ if its presence is unfavorable; $z_{ij} = 0$ when it is absent or unevaluated. The characteristic values at the cell i and at the n cells are defined as

$$c_i = a_1 z_{i1} + a_2 z_{i2} + \cdots + a_m z_{im} \quad \text{or} \quad \mathbf{c} = \mathbf{Za} \quad (1)$$

where $\mathbf{a} = (a_1, \cdots, a_m)'$ is the unknown coefficient vector; $\mathbf{c} = (c_1, \cdots, c_n)'$ is the estimated characteristic vector of n cells.

The question now focuses on estimation of the weight parameters $\mathbf{a}$. Let us consider the matching (similarity) coefficient matrix $\mathbf{S}$ between pairs of m characteristics

$$\mathbf{S} = (s_{jk}) = \mathbf{n}^{-1} \mathbf{Z}' \mathbf{Z} \quad (2)$$

where $s_{jk} = \mathbf{n}^{-1} \sum_{i=1}^n z_{ij} z_{ik}$, $j, k = 1, 2, \cdots, m$.

Beginning with the similarity matrix $\mathbf{S}$ in Eq. (2), the weight for each of the m characteristics can be estimated by either square root method (SRM) or principal component method (PCM), which is discussed here for convenience. According to the theorem of spectrum decomposition for a matrix (Johnson and Wichern 1988; Li 2008; Pan and Harris 1992b), the matrix $\mathbf{S}$ can be decomposed as

$$\mathbf{S} = \lambda_1 \mathbf{a}_1 \mathbf{a}_1' + \cdots + \lambda_m \mathbf{a}_m \mathbf{a}_m' \quad (3)$$

where λ_j is the j^{th} eigenvalue of $\mathbf{S}$ and $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_m \geq 0$; $\mathbf{a}_j$ is the j^{th} eigenvector of $\mathbf{S}$ associated with λ_j .

Define $\phi_j = \lambda_j / \sum_{k=1}^m \lambda_k$, $j = 1, 2, \cdots, m$. Clearly, $1 \geq \phi_1 \geq \cdots \geq \phi_m \geq 0$, since matrix $\mathbf{S}$ is generally a non-negative definite matrix. If ϕ_1 is large enough (e.g., 0.8), matrix $\mathbf{S}$ can be approximately represented by its first eigenvector without losing much information about variability, that is,

$$\mathbf{S} \approx \lambda_1 \mathbf{a}_1 \mathbf{a}_1' \quad (4)$$

Therefore, it is reasonable to define coefficients in the characteristic model (1) as the first principal component: $\hat{\mathbf{a}} = \mathbf{a}_1 = (a_{11}, a_{21}, \cdots, a_{m1})'$. Consequently, the characteristic model is estimated by

$$\hat{\mathbf{c}} = \mathbf{Z} \hat{\mathbf{a}} \quad (5)$$

where $\mathbf{Z}$ is the $[n \times m]$ matrix containing observations of the m characteristics on n cells. The characteristic vector $\hat{\mathbf{c}}$ is often

interpreted as favorability indexes of the n cells to the mineral occurrence of interest.

A major advantage of CA is its simplicity, rendering it easily understood by geologists. Another appealing feature of the method is that it consists of quantitative procedures by which different modes of geological data pertinent to mineralization can be quantified, integrated, and analyzed. However, CA using the first principal component (FPC) as the weights of multiple characteristics is subject to ambiguity of its estimates, since FPC accounting for the largest variability among the characteristics does not necessarily have anything to do with the mineral occurrence of interest. Another major limitation is lack of statistical means that can be used to validate statistical significance of the characteristic estimates.

Favorability Analysis

As discussed early, characteristic analysis presents possible ambiguities in the meaning of favorability function, namely, favorability estimates may not carry sufficient information about the mineral occurrence of interest. This ambiguity is significantly reduced by incorporating target variables in the favorability modeling (Pan 1989; Pan and Harris 1992a). Canonical favorability model (CFM) constructed by maximizing the total covariance between favorability function and preselected target variables has explicitly linked the favorability estimates to the mineral potentials of interest (Pan 1993a).

Let $\mathbf{Z} = (Z_1, Z_2, \cdots, Z_m)$ be the vector of m explanatory variables. The generic form of favorability model is defined as

$$\mathbf{F} = \mathbf{Za} = a_1 \mathbf{Z}_1 + a_2 \mathbf{Z}_2 + \cdots + a_m \mathbf{Z}_m \quad (6)$$

where $\mathbf{F}$ is called the favorability function of explanatory variables $\mathbf{Z} = (Z_1, \cdots, Z_m)$; $\mathbf{a} = (a_1, \cdots, a_m)'$ is an unknown coefficient vector. A more generalized form is

$$\mathbf{F}^w = \mathbf{ZWa} = a_1 w_1 \mathbf{Z}_1 + a_2 w_2 \mathbf{Z}_2 + \cdots + a_m w_m \mathbf{Z}_m \quad (7)$$

where $\mathbf{F}^w$ is called the weighted favorability function; $\mathbf{W} = \text{diag}(w_1, \cdots, w_m)$ with w_j being a priori selected weight for $\mathbf{Z}_j$.

A priori information which should be independent of the information contained in the explanatory data is not always available. An appropriate description of such information requires a thorough understanding of geological features and their intrinsic relations to the mineralization processes.

The favorability functions in Eqs. (6) and (7) are meaningful only with respect to certain stated objectives pertinent to the target variables $\mathbf{Y} = (Y_1, Y_2, \cdots, Y_t)$, which will be incorporated in the estimation later. In mineral exploration, $\mathbf{F}$ is interpreted as the favorable level to the mineralization

represented by the target variables given a collection of observations on explanatory variables.

Favorability function F in CFM is estimated such that it characterizes the maximum correlation between explanatory and target variables. In order to characterize the largest variability and removal of multicollinearity, the target variables are converted to their principal components using the covariance matrix of target variables.

Let $Y = (Y_1, Y_2, \dots, Y_t)$ be the vector of t target variables and its covariance matrix $\Sigma_{YY} = [\text{Cov}(Y_j, Y_k)]$. Let P_k be the k^{th} principal component of the target variables

$$P_k = Y u_k = u_{1k} Y_1 + u_{2k} Y_2 + \dots + u_{tk} Y_t, \quad k = 1, 2, \dots, t \quad (8)$$

where $u_k = (u_{1k}, u_{2k}, \dots, u_{tk})$ is the coefficients of the k^{th} principal component; $\text{Var}(P_k) = \lambda_k^2$ (the k^{th} largest eigenvalue of Σ_{YY}) and $\text{Cov}(P_j, P_k) = 0$ ($j \neq k$).

Suppose that the first q ($\leq t$) principal components account for a sufficiently large proportion of the total variability in the t target variables ($>80\%$). Then, the total variability in t target variables can be approximated by its q ($\leq t$) principal components corresponding to the first q largest eigenvalues, that is

$$P = (P_1, P_2, \dots, P_q) = YU \quad (9)$$

where $U = (u_1, u_2, \dots, u_q)$ be the $t \times q$ matrix containing the q eigenvectors associated with the first q largest eigenvalues of Σ_{YY} .

Consider the criterion to determine the coefficient vector a in Eq. (6) by maximizing the sum of the squared covariance between favorability function F and each of the q principal components P_k . Let

$$\phi^2(a) = \sum_{k=1}^q \text{Cov}^2(P_k, F) \quad (10)$$

with covariance function

$$\text{Cov}(P_k, F) = \text{Cov}(Y u_k, Z a) = u_k' \Sigma_{YZ} a, \quad k = 1, 2, \dots, q \quad (11)$$

where Σ_{YZ} is the covariance matrix between Z and Y . Thus, Eq. (10) is rewritten as

$$\phi^2(a) = \sum_{k=1}^q a' \Sigma_{YZ}' u_k u_k' \Sigma_{YZ} a = a' H a \quad (12)$$

where

$$H = \Sigma_{YZ}' U U' \Sigma_{YZ} \quad (13)$$

The variance of F is given by

$$\alpha^2(a) = \text{Var}(F) = a' \Sigma_{ZZ} a \quad (14)$$

where Σ_{ZZ} is the covariance matrix of explanatory variables Z . Using Eqs. (12) and (13) and Lagrange multiplier μ , construct the following objective function

$$L(a, \mu) = a' H a - \mu (a' \Sigma_{ZZ} a - 1) \quad (15)$$

The coefficients a are selected such that L is maximized. Taking the first-order partial derivatives of function L with respect to a and μ , and setting them to zero, we derive

$$H a = \mu \Sigma_{ZZ} a, \quad a' \Sigma_{ZZ} a = 1 \quad (16)$$

Obviously Σ_{ZZ} is required to be nonnegative definite such that $\Sigma_{ZZ} = \Sigma_{ZZ}^{1/2} \Sigma_{ZZ}^{1/2}$. Hence, Eq. (16) can be rewritten as

$$\Phi e = \mu e, \quad e' e = 1 \quad (17)$$

where $e = \Sigma_{ZZ}^{-1/2} a$ is the unit eigenvector associated with the largest eigenvalue of Φ

$$\Phi = \Sigma_{ZZ}^{-1/2} H \Sigma_{ZZ}^{-1/2} \quad (18)$$

Finally, the estimate of favorability function in Eq. (6) is given by

$$\hat{F} = Z \Sigma_{ZZ}^{-1/2} e \quad (19)$$

Similarly a priori weighted favorability function in Eq. (7) is estimated by

$$\hat{F}^w = Z W \Sigma_{ZZ}^{-1/2} e \quad (20)$$

Equations (6) and (7) are called population estimates of the favorability function. The sample version for a given sample of n observations on all explanatory and target variables can be estimated using the same canonical correlation approach above. Details can be found in Pan (1993a).

Interpretation of the favorability estimates can be aided by estimating various correlation coefficients between favorability function and explanatory and target variables as well as the principal components of target variables. Given the optimum estimate of a , correlation vectors between $\langle F, Z \rangle$, $\langle F, Y \rangle$, and $\langle Z, Y \rangle$ all can be estimated and used for validation of the favorability relations between target and explanatory vari-

ables (Pan 1993a). These correlation estimates provide a powerful tool to gain insights into intrinsic relationships between target and explanatory variables.

Several steps are required to implement the CFM in mineral potential mapping. The foremost important step is to identify and construct target variables and explanatory variables. The data sets or map layers are preprocessed, if necessary, to remove noise and to enhance important signals for the deposits of interest. A complete database for both target and explanatory variables can be constructed in the control area consisting of complete information. Such data will serve as the “training” information in the estimation of favorability function.

The favorability function established in the control area is then extrapolated into the entire study region outside the control area by using an equal-area grid cell approach. For convenience of interpretation, the favorability estimates can be regularized into the range $[0, 1]$ with 1 to be the highest favorability to the mineralization of interest and 0 the least favorable (Pan 1993a, b, c). The map of showing favorability patterns is superimposed by the maps of known deposits or mineral occurrences in the control area for cross validation. The targets can be delineated in the areas where favorability values are greater than some preselected cutoff. Using the estimates of correlation coefficients, each selected target can be evaluated and interpreted in terms of different combinations of explanatory and target variables. This can help eliminate spurious targets created by the observations of less accuracy. Fig. 1 shows an example of the targets selected by CFM in an epithermal gold-silver mineralization district.

Canonical favorability model (CFM) creates a unique, optimal, and flexible linear function for mineral target definition and delineation based on explanatory and target variables. It is optimal in the sense that favorability estimates are derived from maximization of the total correlation between favorability function and target variables. Note that the optimization is valid only when variables are not correlated in spatial locations. In reality, however, most geoscience variables are spatial and their valuations are relevant to geographical locations. Variables are not only correlated each other but also correlated themselves in different spatial locations. CFM, which only captures information on variable values, is not capable of capturing the spatial information of variables associated with geographical locations. As such, more sophisticated favorability methods, such as Indicator Favorability Analysis and Regionalized Favorability Analysis, were proposed by Pan (1993b, 1993c) to capture the information of spatial association in addition to the nonspatial correlations.

Concluding Remarks

An advantage of quantitative integration by favorability analysis comparing to subjective approach is to create unique measures in selecting exploration targets. A favorability map by CFM, for example, shows clear statistical patterns and values that highlight favorable degrees for mineral occurrences. Areas containing the highest favorability estimates are retained for further exploration. Conversely, areas with the lowest favorability values are removed from further consideration. The outcomes of favorability analysis serve as useful gauge for ranking of promising areas, from which top targets will receive the top priority in further exploration efforts.

In a broader sense, successful modern mineral exploration brings together multiple disciplines and bodies of knowledge. The discovery and development of an economic ore deposit require objective and scientific decisions in each of the development stages. The following are considered the primary components necessary for a successful exploration program:

- Geoscience theories to identify favorable areas and to guide the acquisition of incremental information, for example, geology, geochemistry, geophysics, and remote sensing.
- Spatial database management systems to optimally organize the exploration information of diverse forms and to efficiently support daily exploration activities.
- Mathematical tools that calculate or estimate favorability or probability values to describe the degrees of mineral potential which aids the selection of top targets.
- Further exploration or drilling investments to verify the target areas selected in the previous step and to work toward new discoveries.
- Economic decision analysis to perform financial and risk analysis and to ensure appropriate resource development, if a discovery is made.

The quality of favorability analysis largely depends on the quality of the input information. Garbage-in will always result in garbage-out. The early quantitative models, although important demonstrations, were less than impressive geologically because of their limited content of geoscience information. Although these models contained many quantified geological variables, their collective information about the genesis, concentration, and preservation of mineral deposits was meager at best. That objective could not be achieved solely by using more sophisticated and powerful “number crunching” methods. The quantified geology was anemic in information about the formation and preservation of mineral deposits (Harris and Pan 1990; Pan and Harris 1993). The notion of Information Synthesis was initially developed to improve the power of quantitative data integration (Pan and Harris, 2000). The favorability analysis like CFM was an

effort toward the goal of increasing information in mineral potential mapping.

Traditional favorability modeling has been conducted using regular inter-grids or cells as the sampling scheme and estimation unit. The “cell” approach is associated with several drawbacks. The most significant problem is that geological processes can be reconstructed through observable geoscience features, which are measurable in geological units, not artificial cells. The cell-based measurements tend to distort the intrinsic relations between geological features and mineralization descriptors. The cell-based quantification of geological features, spatially correlated and even connected, is difficult to capture essential genetic factors that played key roles of metal enrichment. Moreover, the cell-approach easily ignores exceptional conditions for formation of large deposits, which cannot be readily quantified through grids.

As such, the notion of Intrinsic Geological Unit (IGU) or Intrinsic Sample (IS) was proposed as a sampling framework on which favorability analysis for mineral potential mapping is conducted (Pan 1989, 2010, 2018). This domain-based sample reference ensures the use of consistent geological areas as the units of quantification and interpretation. Thus, instead of estimating statistical relations on the quantified geology and discovered resources of cells, they would be estimated on the characteristics of intrinsic samples. Furthermore, the IGU methodology also makes it convenient to incorporate more geoscience information from the third dimension (depth) in mineral potential mapping.

Fisher, Ronald A.

Frits Agterberg

Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Biography

Sir Ronald Aylmer Fisher (1890–1962) was born in London, England. Many consider him to be the most important mathematical statistician of the twentieth century. In 1909, he was awarded a scholarship to study at Cambridge University where he obtained a First in mathematics in 1912. From 1919 to 1933, Fisher worked at the Rothamsted Experimental Station developing and applying statistical techniques in agriculture and other fields of science. Next, he became the head of the Department of Eugenics at University College, London. In 1937, he helped P.C Mahalanobis establish the Indian Statistical Institute. From 1940 to 1956, Fisher was a professor at Cambridge University. After his retirement in 1957, he went to Adelaide, Australia, where he was senior research fellow of the Commonwealth Scientific and Industrial Research Organisation (CSIRO) until 1962.

His life is described in detail by his daughter Joan Fisher Box (1978). Until Fisher began his career in Rothamsted, the emerging discipline of mathematical statistics was dominated by Karl Pearson who introduced *inter alia* the Pearson correlation coefficient and the chi-square test for goodness of fit in contingency tables. With respect to these two inventions, Fisher (1915) derived the formula of the correlation coefficient in a two-dimensional normal distribution, and he obtained the correct formula for the number of degrees of freedom to be used in goodness of fit tests (Fisher 1922). Later, he developed many other methods often related to analysis of variance. His first book “*Statistical Methods for Research Workers*” (Fisher 1925) went through 14 editions. Later books included “*The Design of Experiments*” (Fisher

1954). He dominated mathematical statistics worldwide during the first half of the twentieth century.

Fisher had a profound interest in geology. In Fisher (1954), he suggested that geology started out on a quantitative path with Lyell (1833) who wrote *Principles of Geology*. This book contained a 60-page long statistical appendix documenting the subdivision of the Tertiary into stages such as Oligocene and Pleistocene on the basis of their contents of fossil species still living today. According to Fisher, this statistical appendix was omitted from later editions of the book, because during the next 100 years geology evolved as a descriptive, nonmathematical science. Lyell's original idea later became a corner stone of quantitative biostratigraphy. It also fits in with Darwin's later theory of evolution. In genetics, Fisher extensively used mathematical modeling to further develop Mendelian genetics.

In "Dispersion on a Sphere," Fisher (1953) describes a method to treat directions of remanent magnetization in basaltic lava samples originally collected by a graduate student at Cambridge University. The resulting "Fisher distribution" has formed the basis of statistical analysis of measurements in paleomagnetism. In invited talks near the end of his career, Fisher advocated Wegener's original theory of continental drift postulating that paleomagnetic data indicate "large movements of crustal blocks." This was about 10 years before geoscientists generally accepted this idea.

Fluid dynamics in porous media

Definition

Flow in porous media is the movement of fluids through the connected pores of a porous material. In the field of geosciences, flow in porous media is typically associated to the movement of groundwater, oil, gas, and other fluids naturally or artificially occurring across geological formations. For instance, aquifers are porous reservoirs in which groundwater flows. Several laws have been derived to quantify flow in porous media, starting from Darcy's law in 1856. Multiple analytical and numerical solutions have been developed to resolve the partial differential equations describing flow in porous media. Other processes, such as mass (solute) and energy (heat) transport, as well as biogeochemical reactions occurring in the subsurface, are directly connected to flow in porous media. Flow in fractured media can be treated as a special case of flow in porous media. Quantifying flow in porous media is notoriously complicated by the limited accessibility to the subsurface, by the lack of data and by the scale dependency of properties and parameters. Uncertainty must be accounted for when dealing with flow in porous formations.

Principles

The concept of flow in porous media is widely utilized in many fields of geosciences. Some well-known applications include: groundwater applications, such as aquifer balance calculations, groundwater well extractions, or managed aquifer recharge; oil and gas extraction from geological reservoirs; aquifer contamination analysis, including transport of reactive biogeochemical species; consolidation and subsidence; saltwater intrusion and salination; storage of energy (heat/cold) in aquifers; CO₂ sequestration in deep geological formations; and nuclear waste storage. The following text addresses mainly groundwater flow in porous media, recognizing, however, that most of the concepts hereby presented can be still applied for other fluids.

Similar to heat and electrical current flows, fluid flow through porous media is a mechanical process, which involves a potential for flow through porous media, i.e., a mechanical energy per unit mass of fluid. A porous material is composed of two parts: the solid matter (or matrix) and the void (or pore) space. The pore space can be occupied by a single fluid phase (e.g., water, air) or by two or more coexisting phases. Total porosity (ϕ) can be defined as:

$$\phi = \frac{V_v}{V_T} \quad (1)$$

where V_v is the void volume and V_T is the total volume of a unit of soil or rock. Total porosity can range from near 0% to

more than 60% depending on the type of geological material, its genetic features, and the physical and chemical processes (e.g., weathering, faulting processes, consolidation, or chemical dissolution) that may have modified the void space with time. Domenico and Schwartz (1990) adopted the terms “the primary porosity” for interstitial porosity and the “secondary porosity” for fracture or solution porosity.

When a pressure difference occurs between two points of a fluid-invaded porous medium, such fluid can flow through the connected pores. The principles of flow mechanics are essentially the same for all fluids, although the scales at which this flow occurs depend on the property of the medium (e.g., permeability), of the fluid (e.g., viscosity and density), and the relative saturation of each fluid in the pore space for multiphase flow.

The first fundamental law describing fluid flow in porous media is Darcy’s law (Darcy 1856). It was first presented by the French engineer Henry Darcy to quantify the results of sand column experiments developed for the water filtration systems of the city of the Dijon in France. Darcy’s law is an empirical law that states that the specific discharge of a flow tube, q (i.e., the volumetric discharge Q divided by a cross section A of the flow tube) is directly proportional to the difference in pressure (P) at the two edges of a flow tube, i.e.:

$$q = \frac{Q}{A} = -\frac{k}{\mu} \nabla P \quad (2)$$

where k is the permeability of the medium and μ is the viscosity of the fluid. The minus sign indicates that flow occurs from higher to lower potential. Darcy’s law is also often expressed in terms of difference in hydraulic heads (h), i.e.:

$$q = -K \nabla h \quad (3)$$

The term K is the hydraulic conductivity of the medium, representing a macroscopic parameter that lumps together the microscopic behavior of the fluid moving in the porous media. As the gradient is dimensionless, the units of q and K are the same (a length over a time, i.e., a velocity). From (3), a pore velocity v can be calculated as:

$$v = q / \phi_e \quad (4)$$

where ϕ_e is the effective porosity, defined as the part of the porosity that is available for the fluid flow.

Darcy’s law is valid for slow, viscous flow approaching the laminar flow conditions (Reynold’s number close to one). While Darcy’s law was originally conceived as an empirical law, it can be rigorously derived from a microscopic description of fluid flow. For instance, it can be derived from the Navier-Stokes equations under the assumption of stationary, creeping, and incompressible flow, with viscous resisting

forces being linear with the velocity. Modifications to the input parameters render Darcy’s law still valid for multiphase flow analysis, such as in the case of water flow in the vadose zone or oil-water systems. A relative permeability factor (k_r) is introduced to scale the saturated hydraulic conductivity K as a function of the phase saturation.

While Darcy’s law has been demonstrated to hold true for a vast number of applications, there are cases when it does not apply. Mitchell and Soga (2005) described at least three scenarios by which nonlinearity between flow velocity and gradient occurs: (1) non-Newtonian water flow properties, (2) particle migrations that cause blocking and unblocking of flow passages, and (3) local consolidation and swelling that is inevitable when hydraulic gradients are applied across a compressible soil.

The interested reader may refer to several text books and monographs (e.g., Bear 1972; De Marsily 1986; Freeze and Cherry 1979) for more information on the topic.

Quantifying Flow in Porous Media

Quantifying flow in porous media can be attained through multiple direct and indirect methods (see, e.g., Delleur 2010).

Direct approaches include: borehole flowmeters, which measure horizontal flow velocity and direction of groundwater flow in wells or piezometers; seepage meters and infiltrometers for measuring groundwater–surface water exchange; solute-based methods such as the borehole dilution test. In karst systems, flow rates can be measured in sinking streams, in cave streams, and in springs. Other methods have been revised, for instance, by Essouayed et al. (2019).

Indirect approaches include the estimation of soil properties to be used in flow models. Such properties can be obtained from laboratory scale experiments (constant or falling head permeameters, which are essentially similar to Darcy’s apparatus – Fig. 1) or through field-scale tests, such as slug and pumping tests. Scale dependency of estimated parameters (e.g., K) is connected to the heterogeneous nature of the subsurface. The importance of a specific scale depends on the type of problem requiring flow estimation. Large-scale tests such as pumping tests can integrate multiple heterogeneities, resulting in an averaged response of the system, and are often preferred by hydrogeologists in practical applications. The principle of pumping well tests is simple. Water is pumped from a well, which is untapping the aquifer. The discharge of the well and the changes in water levels are measured with time in the well and in piezometers close to the pumping well at known distances from the well.

Mathematical models have been developed to support the quantification and prediction of flow in porous media as well as connected quantities (e.g., transport). Flow in porous media is described by partial differential equations (pdes)

Flow in Porous Media,

Fig. 1 On the left, Henry Darcy's portrait and the sand column experimental apparatus, as originally reported in Darcy's 1856 monograph "Les fontaines publiques de la ville de Dijon." On the right, the apparatus scheme, illustrating the difference in hydraulic head ($H_1 - H_2$) at the two edges of the column of length L .

requiring initial and boundary conditions as well as a set of input parameters to be resolved. Analytical or numerical methods can be applied to resolve these pdes. An example of a flow equation for porous media, obtained combining Darcy's law with the continuity equation, is:

$$S_s \frac{\partial h}{\partial t} = \frac{\partial}{\partial x_i} \left(K \frac{\partial h}{\partial x_j} \right) + W \quad (5)$$

where t is time, S_s is the specific storage coefficient ($S_s = S/b$, with S being the storativity or the volume of water released from storage per unit decline in H per unit area of the aquifer, and b the aquifer thickness), K is the second-order tensor of the hydraulic conductivity ($K = K_{ij}$), and W is the sink/source term describing the inflow or outflow volumetric flux per unit volume. In Eq. 5, the system is oriented according to Cartesian coordinates. Alternative coordinate systems can be also adopted. Using radial coordinates, for instance, the flow equation can be written as:

$$S_s \frac{\partial h}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left(rK \frac{\partial h}{\partial r} \right) + W \quad (6)$$

where r is the radial distance. This form is particularly useful when flow gradients are forced by a pumping well.

Analytical solutions provide exact solutions to the governing equation and are often relatively simple and efficient to use. This makes analytical solutions particularly useful for certain applications (e.g., risk assessment) requiring quick analysis without the need of sophisticated codes. For instance, certain solutions of the flow equation are programmable in simple spreadsheets. The problem with analytical solutions is that sometimes the properties and boundaries of the flow system are unrealistically idealized to enable obtaining a closed-form solution of the pde.

The Theis (1935) solution provides an example of a widely adopted analytical model for the assessment of flow in porous media. Recognizing the analogy between heat and flow governing equations, Theis presented the first analytical solution of the transient behavior of groundwater head levels in the proximity of a pumping well. The Theis solution can be written as:

$$h = h_0 + \frac{Q_w}{4\pi T} W(u) \quad (7)$$

where h_0 is the initial head, Q_w is the pumping well discharge rate, T is the aquifer transmissivity ($T = Kb$) and $W(u)$ is the exponential integral

$$W(u) = -0.577216 - \ln(u) + u - \frac{u^2}{2 \times 2!} + \frac{u^3}{3 \times 3!} + \frac{u^4}{4 \times 4!} + \dots \quad (8)$$

with

$$u = \frac{r^2 S}{4Tt} \quad (9)$$

where r is the radial distance from the well where the head change is observed.

Numerical flow models have the advantage that complex boundary conditions and properties can be simulated, such that the flow system is more realistically reproduced. With numerical models, continuous variables are replaced with discrete variables that are defined throughout a spatial grid or mesh. The continuous pde defining the space-time change of h (e.g., Eq. 5) is replaced by a finite number of algebraic equations that defines h at specific points. This

system of algebraic equations generally is solved using matrix techniques. Popular numerical flow models includes MODFLOW (<https://www.usgs.gov/mision-areas/water-resources/science/modflow-and-related-programs>), the open-source groundwater flow model distributed by the U.S. Geological Survey and in use since the end of the 1980s (McDonald and Harbaugh 2003). A variety of graphical user interfaces support modelers with the model implementation. Anderson et al. (2015) provides an excellent reading on advanced groundwater numerical modeling.

An example of a numerical flow code applied to a typical groundwater problem is shown in Fig. 2. A dipole (or doublet) well test configuration is simulated under idealized homogeneous aquifer conditions. This is a widely adopted configuration in many modern practical problems involving flow in porous media, including aquifer thermal energy storage or managed aquifer recharge. A regional groundwater flow occurs from left to right in the figure. The upstream well injects water with a recharge rate Q ; the downstream well extracts water with a discharge rate $-Q$. The problem was resolved using the code MODFLOW-2005 (Harbaugh 2005). To assess the resulting geometry of the streamlines, and particularly to check if the injected water is collected by the

Flow in Porous Media, Fig. 2 An application of a numerical model to resolve a typical problem in hydrogeology involving a dipole (or doublet) well configuration. The code MODFLOW-2005 and

MODPATH were adopted to respectively solve for the groundwater flow system and the particle advection from the injection to the extraction well. The rectangle indicates the zone with higher grid refinement

extracting wells, particle tracking is adopted using the code MODPATH (Pollock 1994). The result of this simple modeling exercise suggests that the downstream well is able to collect the injected fluids.

Open Questions and Unresolved Issues

Research on flow in porous media has advanced dramatically in the last decades. Dealing with quantitative flow analysis in porous media remains however challenging. While some questions have remained open and unresolved for decades, new issues have arisen, particularly those related to new societal challenges (e.g., climate change or environmental pollution) and to technological innovation (e.g., the emergence of supercomputers). A short list of currently debated issues regarding flow in porous media includes:

- Uncertainty analysis. The limited amount of (hydro)geological data characterizing the subsurface, which can be highly heterogeneous, renders flow model outcomes ubiquitously uncertain. Stochastic analysis provides a suitable framework to introduce uncertainty analysis in flow modeling of porous media, casting the model outcomes in probabilistic terms. Statistics (e.g., mean and variance) of desired properties (e.g., h) are used for uncertainty quantification and related applications, including risk assessment (Tartakovsky 2013).
- Scale dependency of flow model properties and parameters. Scaling is the process of relating a property's value on one scale to its value on another scale. Flow measurements in porous media provide properties and parameters that depend on the supporting scale of the measuring approach (Hunt and Sahimi 2017; Pedretti et al. 2016). Such scaling effects are also connected to geological heterogeneity and lack of information regarding the soil structures, in which flow occurs. Finding solutions that resolve the change of model parameters across scales, and particularly the concept of “upscaling” (i.e. the use of coarser-scale homogenized models able to effectively reproduce processes occurring at smaller scales) remains an open question for flow in porous media.
- Combining flow and biogeochemical reactions. Physical and biogeochemical processes are strongly related in porous media. Reactive transport modeling constitutes a major research area in many fields of geosciences, particularly due to the complexity of combining multiple nonlinearly coupled processes with computationally efficient solving tools (Steefel et al. 2014). Reactive transport modeling is needed for a variety of applications, spanning from ecohydrological modeling, in which water, carbon, and nutrients are coupled in the so-called soil–plant atmosphere continuum, to the prediction of chemically unstable radionuclides transport or to acid mine drainage under isothermal or non-isothermal conditions.
- Climate change. Little is still known about the effects of climate change on flow dynamics in porous media. Forecasting of changes in the major climatic variables and accurate estimation of groundwater recharge are two important aspects to consider. Estimating recharge is considered one of the most complicated tasks when dealing with flow in geological media.

Conclusion

Flow in porous media is studied in many areas, from biological sciences to the textile industry. In geosciences, it is typically referred to as the fluid dynamics of geological systems. The occurrence and the magnitude of flow in geological systems is directly controlled by the type of soils, reservoirs, and deposits, and the type of moving fluids. Since 1856, it is possible to quantify flow in porous media through a set of equations first obtained by a French engineer called Henry Darcy, after whom a fundamental law has been named. Research is currently very active to find increasingly efficient methods to measure and predict flow in porous media. Uncertainty analysis must be emphasized as an essential tool to make predictions regarding flow in porous media and related issues (e.g., contaminant transport).

Definition

A stratigraphic model is a conceptual, physical or mathematical representation of the succession of sedimentary layers beneath the surface of the Earth. Historically such models were static representations of the shape, location, and content of existing layers. Such models were initially built through observation of outcrops, drill holes, and excavations, and have been supplemented since the 1920s by remote petro- and geophysical measurements.

Stratigraphic models have formed the basis not only of academic studies, but a significant proportion of the global economy since pre-Roman times, with rock quarrying, gold,

copper, and lead mining, and more recently hydrocarbon extraction and carbon sequestration.

“Forward” and “inverse” models can be both intuitive and formal, mathematical, ways of examining and testing the inductive and deductive reasoning behind stratigraphic model building.

The traditional “inductive” process of geological interpretation of an observed stratigraphic succession can be seen as a process of “inverse” modeling. A geologist intuitively uses understanding based on training and experience to relate the process that formed the stratal succession to the stratigraphic observations. To a large extent this depends on experience and background, rarely quantified and thus highly subjective.

Forward modeling of stratigraphic processes can be seen as a “deductive” means to quantitatively examine and test this intuitive process understanding by modeling the depositional, diagenetic and tectonic processes forward in geological time and comparing the results with observations. This comparison can be a subjective matching of the model with well or outcrop data, or through a numerical inverse model with a defined error or objective function to be minimized. A forward model may be physical, using a flume-tank, or numerical, using computer implementations of the equations and algorithms representing the physical processes of erosion, transport, sedimentation, burial, diagenesis, and tectonic modification of the stratal succession.

An “Inverse model” can mean somewhat different things mathematically, geophysically, and geologically.

Mathematically the “inverse problem” is the process of solving for “y” given:

$$x = \mathbf{M}y$$

where $\mathbf{M}$ is a matrix of functions relating known values “x” to the unknown values “y”.

Geophysically “x” could be a series of surface measurements of gravity, then if “r” is the distance from the surface measurement point to the subsurface body. “y” the matrix of subsurface rock densities and “G” the universal gravitational constant, “ $\mathbf{M}$ ” is the matrix of G/r^2 for each possible combination of measurement and distance to the subsurface body.

If “ $\mathbf{M}$ ” is a square matrix, with no zero eigenvalues, and is not overdetermined, then this linear inverse problem could be solved exactly by inverting the matrix “ $\mathbf{M}$ ”.

Generally, however, this is not possible in practice and the problem must be solved iteratively using additional prior information and/or by minimizing the error between calculated values of “x” and the actual observations. This process involves a “Forward Model” as discussed below.

The mathematical “Forward Model” consists of an expression of a relationship. This could be a simple equation:

$$x = Fy$$

solving for x given a known function F and known values “ y ”.

Geophysically a forward model example could be the production of a simple synthetic seismic trace by convolving an acoustic source wave with a stratigraphic model of layered acoustic impedances.

Introduction

By modeling a system we can test our understanding of its fundamental properties. Such modeling is often called simulation. Simulation is a form of model building, where sufficient features of the system or object being modeled are included to enable predictions to be made (either qualitatively or quantitatively) concerning the behavior of its real-life analogue. Simulation can be physical, for example flume-tank experiments, mathematical (where analytical solutions exist for predictive equations), algorithmic/computational (where numerical solutions exist), or heuristic/computational (heuristic = “rule-of-thumb”), where knowledge exists in the form of general “understanding” and logical rules rather than equations.

Modeling may be either “forward” or “inverse”. In the forward model we start with what we hope are the major processes acting on a system, wave direction and amplitude, for example, and some boundary conditions, such as beach grain-size distribution, water depth, and beach slope. We let the model run for an appropriate length of geological time and look at the change in the system. If both the process model and the boundary conditions were specified sufficiently, then the end result will be a prediction that can be tested at an appropriate scale. In reality, there will always be higher resolution features that were not predicted by the simulation as a result of “aliasing” at the fixed time intervals and fixed grid dimensions used (see Shannon/Nyquist sampling theory), and we have to hope that these are not significant for our proposed use. Note that although recent simulations use unstructured grids and variable time intervals there will still be spatiotemporal features that are below the simulation resolution. An important point to remember about any modeling is that a model is always a simplification in some aspect. The skill of the modeler is to ensure that the model is neither too simple nor too complex to answer the question being asked. Another way of looking at this is to say that if you do not know what question you are asking, then no model will ever satisfy your requirements. There is no such thing as a generally applicable model.

Forward Stratigraphic Modeling

Numerical forward modeling of any type tests our understanding of a system. To paraphrase Lord Kelvin, “if you can’t put numbers on it – you don’t understand it”, In the case of weather forecasting for example we take the physics of water vapor, air mass movement, radiation, convection, on a variety of scales and test our understanding of the system by making predictions (forecasts) into the future – by hours, days, or months. These predictions are tested each time we go for a walk or plan a holiday. Thus forward stratigraphic modeling can also have several goals:

- Quantitatively investigate our current understanding of a particular depositional/stratigraphic process
- Predict useful rock properties away from observations (between wells, below seismic resolution, etc.)
- Test multiple sedimentological working hypotheses
- Form part of an inverse model iteration

Interest in the forward modeling of sediment depositional processes was boosted by the need to model and simulate beach conditions for landing military vehicles during and after the Second World War. Krumbein provides a glimpse of this work in his 1964 paper on process-response models of “beach phenomena” including the modeling of soft and hard sand areas. His “Technical Memorandum No. 3 for the Beach Erosion Board of the US Corps of Engineers” provided equations for beach energy and grain-size relationships (Krumbein 1947).

Krumbein’s work provided an overview of the types of variables and interrelationships which could be included in a model of beach processes. Bates (1953) (quoted in Harbaugh and Bonham-Carter 1970, p. 458) proposed a hydraulic jet model for delta formation which formed the pre-cursor to Bonham-Carter and Harbaugh’s models of the late 1960s and early 1970s. Culling (1960) looked at erosion and transport in the subaerial environment using a potential-gradient approach (the higher the potential energy slope at a given point, the higher the erosion rate).

Sloss (1962) discussed the use of a simple “hole-filling” type of model in which the shape of a stratigraphic body “ s ” was a function of sediment input “ Q ”, rate of subsidence “ R ”, erosion of deposited sediment “ D ”, and the nature of the material supplied “ M ”. The model could simulate the effects of simple rigid-slab subsidence which increased basinwards from a null-point or hinge-line.

The coal extraction industry in Kansas funded work at the University of Kansas and the Kansas Geological Survey during the 1960s (under Dan Merriam) where many stratigraphic modelers cut their teeth on the Carboniferous cyclothems. Schwarzscher (1966) used differential equations

relating sedimentation rate to water depth and subsidence (quoted in Harbaugh and Bonham-Carter 1970, p. 463). Harbaugh (1966) looked at simulating carbonate ecology and sedimentation using an Algol program. In Britain, King (1968) developed a heuristic and stochastic forward model of shingle-spit formation (quoted in Harbaugh and Bonham-Carter 1970, p. 461). Oertel and Walton (1967) developed a conceptual model that included feedback to give a cyclic component to deltaic sedimentation.

Bonham-Carter and Sutherland (1967, 1968) developed Bates' ideas further with computer programs for jet-flow, assuming that as the river enters a larger body of water the flow velocity distribution is as a "plane jet" (Tetzlaff 1987, p. 17). Empirical functions are used to estimate the distribution of different sediment grain sizes. Each grain trajectory is considered independently. The model "realistically" represents deltaic lobes, levees, and mouth bars (Tetzlaff 1987, p. 20).

Harbaugh and Bonham-Carter (1970) further developed Sloss' geometric space-filling model with some refinements. They included sediment-load dependent subsidence and a time-lag that succeeded in modeling sigmoidal chronosomes (bodies of rock bounded by isochronous surfaces) with interfingering grain-size. The model worked in an algorithmic way where the basin floor was divided into a two-dimensional series of columns and sediment was passed into the basin from one end and allowed to accumulate (or not) on any particular column depending on the available accommodation (distance between wave base and previous column top).

Harbaugh and Bonham-Carter (1970) summarized the developments to date and presented examples of different types of flow models (Chaps. 6 through 9). This is one of the most useful introductions to the subject.

Since the 1980s there has been an increase in the number and variety of forward stratigraphic modeling computer programs as discussed in Paola (2000) and Burgess (2012), and the decade to 2021 has seen a rapid increase in the number and variety of practical applications.

Inverse Stratigraphic Modeling

Inverse modeling takes the given, observed, state of a system and tries to derive both its initial state and the processes acting to produce the observed state. In simple physical cases, where a single linear process has acted on a few variables, this may be possible. As an example, a rough estimate of the initial height above a given point of a steel ball rolling down an inclined plane may be derived by measuring the velocity of the ball at that point. If we wanted to predict the initial height to several significant digits however, then we would have to include information about surface roughness, friction, material properties, etc. Note also that in this case we cannot use an

inversion approach to predict horizontal distance of the measurement point from the release point. In the inverse modeling case we have to understand the processes involved and their relation to the question that we wish to ask.

Both forward and inverse models have their weak points. A given present-day state can be derived from an initial set of conditions via several different routes, or a different route combined with different initial conditions can result in an identical present-day state. In other words it is relatively easy to prove sufficiency but almost impossible to prove necessity. A sedimentological example of this is the "upward-coarsening unit," where it is relatively easy to show that a prograding marine unit **can** have produced that grain-size distribution, but impossible to show that **only** a prograding marine unit could have produced it. Both forward and inverse modeling of natural systems suffer from the phenomena of "non-uniqueness." This is the property of being able to approach the same result by an infinite number of different paths. Burton et al. (1987) emphasized the need for prior information in any inverse scheme to constrain the solutions. Today the more-or-less global acceptance of a defensible eustatic curve from the Devonian has provided a valuable (and testable) prior.

One of the most challenging issues in inverse stratigraphic modeling is the choice of an "objective/cost/loss/error function" to be minimized by the inverse scheme. The objective/error function to be minimized should represent the aim of the simulation. For example if the simulation is being run to predict the presence of porous rocks in an unexplored part of a basin, then an appropriate objective function could be the difference between modeled and predicted porosity distribution at a known well location. If there is a large error between the predicted and observed porosity distribution, then the model is wrong in some way and the forward model parameters will have to be changed and the model re-run. A typical (and poorly understood by users) problem here is the difference in **volumetric** resolution of the model and the constraint or test data. Both the difference in volume sampled and the relative measurement/prediction errors need to be understood. All physical measurements sample a volume, and all stratigraphic models predict volumes, but if there is an order of magnitude difference between the two volumes, it is necessary to adjust the objective function accordingly.

In its simplest form, inverse stratigraphic modeling can be achieved by running a group of forward models with systematic changes to the input parameters, using the human eye to select the best model from a visual inspection of the results, then systematically changing the input parameters to and repeating the process. This was described in Wijns et al. (2004):

Underlying most forward modelling exercises in geosciences is an implicit inverse question. A formal inverse approach to

geological modelling has only recently started to develop due mostly to two reasons: first, standard geological modelling is extremely computationally intensive, and second, it is hard to develop numerical cost functions, to drive the inverse search, that can capture enough geological knowledge to make the search meaningful. Creating a cost function is difficult because it involves distilling into a single value an assessment of the geometries, volumes, and positions, as well as determining how geologically reasonable a solution may be.

We employ interactive inversion to tackle the second problem. The concept is of such simplicity as to make it appear as little more than a novelty: replace the numerical evaluation of solution quality with a subjective value provided by an expert user. Underneath the simplicity there is a very powerful concept. We replace what in most cases is an artificial numerical function with the computational power of an expert brain. This provides not only the best 'geological processing power' we currently have, but also intuition and expertise, in the form of theoretical knowledge, experience, and a priori information.

Intuitive as the above approach is, it is also slow, and with large, complex real-world stratigraphic models a computer-based convergence method is needed.

Numerical stratigraphic inverse modeling has a shorter history than forward modeling, which in part reflects its difficulty and reliance on very fast processing power to achieve solutions. Some of the first approaches have been discussed by Lessenger, Cross, and Lerche in various papers in the 1980s; Guérillo, Bornholdt, Nordlund, and Duan in the 1990s; and Duan, Charvin, and Falivene since 2000.

The (fractal-like) incompleteness of the stratigraphic record (Plotnick 1986) at any given location also complicates stratigraphic inversion. Erosion and non-deposition are part of the sedimentation process, but are represented by surfaces rather than sediment bodies. Typically, at any given location, the amount of "missing" geological time exceeds the time represented by sediment.

Forward Stratigraphic Models

Mathematical and computational forward stratigraphic models have evolved in many diverse schools since the 1950s. A good introduction to the basic principles behind these various approaches can be found in Granjeon (1996).

The approaches can be divided into broad subcategories, from the simplest to the more complex as follows.

Geometrical Models

Models that do not describe the process itself, but the geometric results of the process, usually filling or partially filling accommodation space. Many of these models are based on pioneering work by Sloss (1962). He developed a simplistic model for the relationship between sediment shape (**S**), volume (**Q**) of sediment supplied, rate of subsidence (**R**), rate of dispersal of sediment (**D**), and the "nature of the material supplied" (**M**). He developed models for situations where

the relationship between input sediment volume and subsidence rate varied, showing that both regressive and transgressive phases and cyclical patterns of lithosomes (sensu Wheeler and Mallory (1956)) could be generated by sediment supply variation. Sloss's subsidence term implicitly rather than explicitly included relative sea level change (as a uniform subsidence). Sloss discussed the use of the model in passive margin and foreland settings, and also discussed turbidite development. His treatment was on a purely logical, conceptual basis. These ideas were taken up by Harbaugh and Bonham-Carter in Chap. 9 of their 1970 publication, which provides a mathematical treatment of Sloss's conceptual model. The following is taken from this chapter.

A section through the basin topography is divided into a series of two-dimensional columns Δx wide which provide the basis for sediment accumulation.

The basic premise is very straightforward. Sediment enters the section from a predetermined point. Part of the sediment load is deposited on the first column encountered and the remainder is passed to the next column. The amount deposited on a particular column depends on (a) the amount of sediment available for deposition, and (b) the accommodation space in that column. Mass is conserved by accounting for all sediment as it moves throughout the 2D section. The accounting system is very simple. Let the sediment load (mass) entering the basin be L and let the proportion of this load that is deposited on the first column be k . Thus the amount deposited is kL and the remaining load that is transferred to the next column is $L - kL$, or $L(1 - k)$. This can be generalized in that the amount deposited n columns from the start point ($n \cdot \Delta x$ distance units away) is $kL(1 - k)^{n-1}$. The sediment mass entering this column is $L(1 - k)^{n-1}$. The value k relates to the transmissibility of sediment in the direction of mass transport and must be specified beforehand. Different values of k can be used for different grain-size fractions. K is not a physical parameter but is heuristic in nature (Harbaugh and Bonham-Carter 1970, pp. 377–379). The value k can also be interpreted as slope of a particular sediment type. Different sediments may have different k values.

Changes in accommodation space due to relative sea level fluctuation, subsidence, and compaction are handled heuristically by constraining this simple algorithm. Harbaugh and Bonham-Carter (1970, p. 379) discuss three constraints, although more are possible and will be discussed later. The three situations discussed are:

- Where the sediment-water interface is above or equal to base level (as specified for a given particle-size class), then deposition is not allowed and all remaining load is passed to the next cell.
- Where the sediment-water interface is only slightly below base level only part of the sediment load is deposited as a proportion of $kL(1 - k)^{n-1}$. Sediment is base-leveled and the remainder passed on to the next column.
- The sediment-water interface is well below base-level for all particle-size fractions and $kL(1 - k)^{n-1}$ is deposited.

Over the years additional constraints have been added by many packages, such as angle of repose for various grain-size mixtures, slope failure, etc. Subsidence can be either an instantaneous or lagged (occurring after a defined time interval) function of sediment loading or external tectonics. There are in practice few limits to the algorithmic complexity that can be built in to this type of heuristic model. A FORTRAN IV program to carry out this type of modeling is provided by Harbaugh and Bonham-Carter (1970, pp. 382–384), and this program formed the precursor to many of today's geometric models. Quite complex geometries and sedimentological situations can be built in. The relation to physical principles is however tenuous to say the least, and such models function best as tools where full access to the source code is necessary for the programmer-geologist to test ideas expressed as “if-statements” in the code. As a general “off-the-shelf” modeling package they are only of use if the heuristics used are explicitly stated and agree to one's prior assumptions about the way sediments behave in any particular circumstance.

Topography-Control (Diffusion, or Potential-Gradient) Models

Models in which the transport and deposition of sediment is a function of the potential gradient on the preexisting (and continually changing) sediment mass/surface rather than the nature of the preceding cell as is the case in a geometric model. In the following discussion mass-concentration and topographic height (energy potential) are treated as equivalent and interchangeable. In other words a heap of sediment that will slide down-hill (diffuse) is the same as a concentration of sodium ions that will diffuse throughout a block of porous sandstone from a high potential to a low potential. Sediment can be considered to follow the same rules, that is, it is difficult to get sediment to climb uphill.

These models are based on solutions to Darcy flow or Ohms Law type equations: Fick's first law of diffusion states (after Harbaugh and Bonham-Carter 1970, p. 239):

$$J_x = -k\delta_c/\delta_x$$

where:

J_x is the mass flux.

k is the diffusion coefficient.

c is the concentration of material.

x is the coordinate direction parallel to flow and perpendicular to the reference surface.

In its three-dimensional, time-dependent form, derived by combining the first law with an equation of continuity (conservation of mass) such as

“sediment volume in minus sediment volume out equals accumulation of sediment”

For zero accumulation the continuity equation can be simplified to (after Harbaugh and Bonham-Carter 1970, p. 216)

$$\frac{\delta V_x}{\delta x} + \frac{\delta V_y}{\delta y} + \frac{\delta V_z}{\delta z} = 0$$

where V is the volume of an incompressible fluid over time interval t .

In the form of a mass-flux equation this becomes:

$$\frac{\delta J_x}{\delta x} + \frac{\delta J_y}{\delta y} + \frac{\delta J_z}{\delta z} = \frac{\delta c}{\delta t}$$

(Harbaugh and Bonham-Carter 1970, p. 239).

Combining a continuity equation and Fick's first law gives Fick's second law:

$$k \left[\frac{\delta^2 c}{\delta x^2} + \frac{\delta^2 c}{\delta y^2} + \frac{\delta^2 c}{\delta z^2} \right] = \frac{\delta c}{\delta t}$$

where k is an isotropic diffusion coefficient (the same in all directions).

This equation can be modified to give diffusion coefficients that vary with direction, with depth (Rivenaes 1992), with location, and with time.

In its two-dimensional form the equation appears as:

$$k \left[\frac{\delta^2 c}{\delta x^2} \right] = \frac{\delta c}{\delta t}$$

where c is the topographic elevation and x is the distance from an arbitrary coordinate origin.

This is saying that the change in height (elevation) with time at any particular point in a section is a function of a constant times the change in slope at that point. In its finite difference form this equation becomes (after Harbaugh and Bonham-Carter 1970, p. 241, Eq. 6–49):

$$c_{t+1,j} = c_{t,j} + k \left(\frac{\Delta t}{(\Delta x)^2} \right) (c_{t,j+1} + c_{t,j-1} + c_{t,j})$$

which is simply saying that the increase in height at any given location after a time interval Δt is a function of the height (potential) difference between that location and another location Δx away at the previous moment in time. The product of the constant of proportionality “ k ” (the diffusion coefficient) and the time step/column width term:

$$k \left(\frac{\Delta t}{(\Delta x)^2} \right)$$

is constrained to lie within the range of 0.0–0.5. A value zero gives a diffusion rate of zero and there is no change of slope with time (Harbaugh and Bonham-Carter 1970, p. 244). In this form the equation functions in a similar way to the geometric model which adds sediment according to heuristics which replace the single coefficient.

Paola in Angevine et al. (1990, pp. 97–101) discusses the derivation of the linear diffusion equation and the assumptions involved, specifically in the case of fluvial systems.

One practical issue with diffusion-based multi-grain forward models at all scales is the choice of “diffusion coefficients” that have sedimentological meaning beyond the simulation process. A realistic basin-scale simulation requires the definition of many diffusion coefficients for the various geological processes involved, and there are very few studies that relate these values to real measurable sedimentological or environmental processes. The coefficients can be chosen to provide a model result that matches observations to a specified degree, but inverting this result to derive insight into the geological processes is not straightforward.

Hydraulic Process-Response Models

These are models in which fundamental laws concerning hydraulic flow are used in three dimensions to model sediment transport and deposition in three dimensions. Most are based on solutions to simplified versions of the Navier-Stokes equations describing flow in three dimensions for an isotropic Newtonian fluid. The book by Tetzlaff and Harbaugh (1989) provides a useful introduction to this type of modeling. The following passage is taken from Tetzlaff and Harbaugh (1989, p. 14).

“The Navier-Stokes equations combine the continuity equation (Eq. 1) and the momentum equation (Eq. 2) to provide a mathematical description of flow for an isotropic Newtonian fluid. An isotropic Newtonian fluid is a fluid whose properties are uniform in all directions and that follows Newton’s laws of motion.

The continuity equation incorporates the conservation of mass:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \mathbf{q} = 0 \quad (1)$$

where

ρ = fluid density

t = time

$\mathbf{q}$ = flow velocity vector

whereas the momentum equation describes changes in momentum by the fluid:

$$\rho \left(\frac{\partial \mathbf{q}}{\partial t} + (\mathbf{q} \cdot \nabla) \mathbf{q} \right) = -\nabla p + \nabla \cdot \mu \mathbf{U} + \rho(\mathbf{g} + \Omega \mathbf{q}) \quad (2)$$

where

p = pressure

μ = fluid viscosity

$\mathbf{U}$ = Navier-Stokes tensor

$$= \begin{bmatrix} 2\frac{\partial u}{\partial x} - \frac{2}{3}\nabla \cdot \mathbf{q} & \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} & \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \\ \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} & 2\frac{\partial v}{\partial y} - \frac{2}{3}\nabla \cdot \mathbf{q} & \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \\ \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} & \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} & 2\frac{\partial w}{\partial z} - \frac{2}{3}\nabla \cdot \mathbf{q} \end{bmatrix}$$

u, v, w = components of flow velocity $\mathbf{q}$ in the direction of x, y , and z axes, respectively,

Ω = Coriolis tensor

$$= \begin{bmatrix} 0 & 2\omega \sin \phi & -2\omega \sin \phi \\ -2\omega \sin \phi & 0 & 0 \\ -2\omega \cos \phi & 0 & 0 \end{bmatrix}$$

ω = angular rotational velocity of the earth

ϕ = latitude

$\mathbf{g}$ = gravitational acceleration vector

If the fluid is homogeneous, incompressible, and remains at constant temperature, the density ρ and viscosity μ can be considered constant”.

Although the Coriolis acceleration $\Omega \mathbf{q}$ is so small in most deltaic simulations that it can be ignored, marine currents on an oceanic scale are strongly affected by the Coriolis acceleration, which should therefore be included for basin-scale models.

Sediment transport and deposition within this flow regime is another, separate, problem. One solution uses a bed-load transport equation that transports sediment as a function of bed roughness, flow depth, and flow rate.

Comparison Between Various Equations for Bed-Load Transport

Author	Formula
DuBoys (1879)	$Q_s = B_1 n^4 \frac{Q^4}{h^{2/3}}$
Meyer-Peter and Muller (1948)	$Q_s = B_2 n^3 \frac{Q^4}{h}$
Shields (1936)	$Q_s = B_3 \frac{n^4}{d} \frac{Q^4}{h^{2/3}}$
SedSim (1980)	$Q_s = B_4 \frac{n^2}{h^{1/3}} Q^4$
Q_s = sediment discharge rate	B_i = constant
n = Manning's roughness coefficient	d = sediment particle diameter
Q = water flow rate = $ Q $	h = flow depth

Some of the more successful 3D hydraulic process-response models use a combined Eulerian/Lagrangian “Marker-in-Cell” approach (Harlow 1964) that allows intra-cell fluid vectors to be used to simulate 2.5 dimension free-surface flow under many flow conditions.

Recent models include Delft3D (Lesser et al. 2004; Flores 2011) and Badlands (Salles and Hardiman 2016).

Mixed Algorithmic, Heuristic, and Fuzzy-Logic Models

In this case a pragmatic/heuristic mixture of model is used under different circumstances. For example, large-scale clastic features may be filled geometrically/by diffusion, while carbonates use a partial process model, and coal is deposited heuristically. The Shell model “StrataGem” operated in this way (Lawrence et al. 1987). FUZZIM is a model that uses fuzzy-sets and fuzzy-rules to model three-dimensional stratigraphy (Nordlund 1999a, b). Other modeling approaches are described by Ritchie et al. (1999), and Lessenger (1993), Lessenger and Cross (1996), Lessenger and Lerche (1999). Duan has modeled carbonates (Duan et al. 1998) as has Bosence et al. (1998).

Inverse Stratigraphic Models

As stated previously, the process of geological study is one of inference or inversion, the attempt to understand the earth's history through intuitive or numerical process understanding.

The sediments are a sort of epic poem of the earth. When we are wise enough, perhaps we can read in them all of past history. (Carson 1951)

The stratigraphical record is a lot of holes tied together with sediment. (Ager 1973)

Our best record of past conditions on Earth, for most of its history, comes from strata in sedimentary basins. Clues to this history are housed in the composition, spatial organization, chemistry, and fossils of strata. The record allows us to interpret the Earth system response to past episodes of climate change. These interpretations are not only important for characterizing Earth's past but also aid our ability to predict responses to ongoing climate change. To read Earth's epic poem, though, we

must solve one of the most complicated inverse problems known to science (Straub et al. 2020).

Stratigraphic inverse problems are nonlinear and generally not solvable analytically.

In general terms, properly formulating and solving a stratigraphic inverse problem demands that one has:

1. A very good understanding of the physical processes and how they may be simplified, e.g. at its simplest, a sedimentary basin consists of accommodation filled with sediment at a certain rate, from certain locations over a certain time period
2. Good experimental strategy and quality measurements
3. Most importantly, effective computational techniques

Without a good understanding of the physical processes, basically nothing can be done. Quality measurement data are essential because they will decide the quality of the solution of the inverse problem. This includes not only the accuracy of the observational or experimental data but also the precise knowledge of the characteristics of the measurement data in terms of the noise content (noise level, frequency, etc.).

Stratigraphic observational data are problematic in this context. Outcrop data exist because the strata at that location are somehow atypical (more resistant to weathering/faulted/etc.) – the rest have been eroded away. Aerial/satellite imagery are snapshots of a current process, possibly transient and atypical for that transient environment. Well/core data are sparse in most parts of the world and the well locations are often not selected to represent the average strata but some atypical feature of economic interest.

To numerically solve the inverse problem in stratigraphy, a numerical forward model is necessary. As discussed in the section on forward stratigraphic modeling, a wide range of numerical forward model types are available. However, due to the iterative nature of inverse modeling there are specific requirements of a forward model that are necessary as part of an inverse scheme:

For inverse modeling purposes the forward stratigraphic model should:

- Make predictions that are directly comparable to real, measurable, stratigraphic data
- Simulate those aspects of stratigraphy that are of interest in a specific study (e.g., “location of offlap-break over time,” or “porosity of Permian sands in an undrilled part of the basin,” or “timing and character of carbonate deposition in the basin”)
- Simulate necessary and sufficient processes for the depositional system being investigated
- Be capable of implementation on a digital computer and have as short a run time as possible
- Have an appropriate spatial and temporal resolution

The outputs from the forward model should be independent and as sensitive as possible to the system parameters to be inversely identified. For example, marine stratal patterns evolve in space as a function of the relationship between accommodation and sediment supply. Accommodation can change as a function of initial topography, tectonic subsidence, sediment accumulation, sea level change, isostatic response, etc. The inverse model could attempt to identify all or some of these variables, or simply invert for change in accommodation in space and time.

The simplistic basic requirements of several inverse modeling schemes are as outlined in the pseudo-code below (from Alazzam and Lewis (2013)):

```

Define objective function (g)
Initialize the values for all parameters: m, t
Generate (m) feasible solutions from the search space using a forward model
    Evaluate the fitness from the objective function (g)
    Optimal solution = the best solution.

i=1
Do while i < t,
    Generate m/2 solutions from the neighbourhood of the best solution
    Generate m/2 solutions from the search space
    Find the best solution from the (m) generated solutions

    If the best solution is better than the optimal solution
        Optimal solution=best solution
    End If
End DO

```

The various components of this scheme have changed over the past 40 years, which is an indication of the difficult nature of the problem. Taking each component in turn:

Define objective function (**g**)

g – the objective function – is a “fit for purpose” measure of success in matching the model with some aspect of reality. It is often expressed as a numerical distance to approach zero in a successful simulation, but can be a visual comparison between a complex model and reality (see Wijns et al. 2004) or the shape of a sedimentary feature (Zhang et al. 2021). Stratigraphically it could be the thickness and modal grain sizes of the strata at one or more known well locations.

Initialize the values for all parameters: **m**, **t**

Generate (**m**) feasible solutions from the search space using a forward model

This step involves running the forward model using either a selection of values sampled using a variety of approaches

from the permissible ranges for each variable in the forward model, or a subset of the variables with others being pre-determined (e.g., an assumed eustatic curve and a sediment compaction rate).

In a “genetic” inverse model these variable values may be coded as a binary string (Bornholdt et al. 1999) since mutations on a binary string affect each order of magnitude with equal probability.

In a Bayesian Monte Carlo Markov Chain (MCMC) approach (Charvin et al. (2009a, b), Gilks et al. (1996)):

the total problem for inversion is to understand the uncertainty on this optimal, or best, model, or distribution of all possible models. Both aspects require some quantitative measure of how well a given model can reproduce the observed data. This is known as the misfit or likelihood function, the latter of which can be thought of as a measure of the probability of reproducing the observed data, given a model with a particular set of parameter values. This can be written as $p(D_{obs} | X)$, where $a | b$ means a given, or conditional on, b .

The aim of the inversion scheme is to construct a reliable representation of the posterior probability distribution $p(D_{obs} | X)$. Given this, it is then straightforward to extract individual models (e.g. the best or expected model), to construct probability distributions for individual model parameters, and to examine correlations between parameters. One widely used method to achieve these goals is Markov chain Monte Carlo (MCMC), a stochastic sampling-based approach. MCMC algorithms aim to construct a random walk around the model space (i.e. a Markov chain) which has the posterior probability distribution as its limiting stationary distribution. Useful introductions to this methodology are given in Gilks et al. (1996) and Denison et al. (2002). In a few words, MCMC operates by generating a large number of samples from the model space, according to well-defined rules, and the distribution of those samples provides a good approximation of the underlying posterior distribution. Charvin et al. (2009a, b)

Surrogate models may be used to reduce the computational cost associated with uncertainty propagation of the most relevant inputs to a selected range of outputs (Gervais et al. 2018).

Evaluate the fitness from the objective function (**g**)

Where “fitness” is the measure of the best “match” to the objective function or the minimum distance to data. This could be a simple regression r^2 value in the case of a series of thicknesses at a well, or an N-dimensional matrix.

In the case of string matches at well locations (Duan 2017) has shown that the Levenshtein distance (Levenshtein 1966) is useful from the point of view of sedimentology and stratigraphy “where comparison of sedimentary facies successions should account for the following aspects: (1) facies types and their division in sections, including special facies such as erosional surfaces; (2) the thickness of each identified and divided facies (maybe repeated) in sections; and (3) the vertical order or sequence of the coded facies in each

sedimentary facies succession.” The Levenshtein distance is also capable of allowing for facies changes according to Walther’s Law (facies in neighboring depositional environments tend to be adjacent in vertical succession’).

The choice of objective function in inverse modeling is critical. There is a tendency to use mathematical solutions taken from non-stratigraphic studies rather than those that can have direct “stratigraphic fitness” such as conforming to Walther’s Law or chromosome dimensions.

Optimal solution = the best solution.

The best combination of input variables as defined by the fitness is then used as a good measure for the local optimal solution and it is also initially set as the best known solution for the next iteration.

Do while $i < t$,
Generate $m/2$ solutions from the neighbourhood of the best solution

In the next iteration, take the best solution and use variable values close to those from the fittest to form $m/2$ new simulations

Generate $m/2$ solutions from the search space

Use variable **values from the entire variable set** to form $m/2$ new simulations to add to the fittest.
Calculate the fitness for all m simulations.

Find the best solution from the (m) generated solutions

If the best solution is better than the optimal solution
Optimal solution=best solution
End If
End DO

Lessenger and Lerche (1999) discuss the strategy and tactics of inverse model construction in stratigraphy.

Current Investigations, Controversies, and Gaps in Current Knowledge

The above Forward Stratigraphic Modeling categories are to some extent arbitrary, and there is a good deal of overlap in practice in many operational programs. The difference between the models is becoming blurred as commercial pressure forces developers to include features that cannot be handled by one approach alone. There remains however room for all types of model at appropriate scales. For studying the entrainment, transport, distribution, and deposition of clastics in locations such as beaches, harbors, and estuaries over short time intervals and at resolutions of a few meters then hydraulic process models are of interest, such as Delft3D and Sedsim. For pipe-line scour studies, platform and

loading-quay effects on sediment build-up, and pollutant dispersal including heavy minerals from drilling operations, and cases where basin/channel topography is complex and the problem is three-dimensional in nature and short-term, then Delft3D may be appropriate.

A new generation of parallelized, unstructured grid models such as Badlands, and those based on Python code are now available (Salles and Hardiman 2016; Salles et al. 2018a, b).

Limitations to Present Models

Explicit numerical forward stratigraphic modeling of cohesive clays and flocculation is limited to a few high resolution/short time interval studies at present, and given the influence of flocculated clays on channel migration in deltaic environments this could be an area of interest in future.

The explicit inclusion of vegetation in forward stratigraphic models is also a potential future area of interest as dune stabilization by vegetation is a major preservation mechanism (Salles et al. 2011), and the role of mangroves and seagrass as sedimentation and erosion controls in tropical littoral environments needs to be explicitly modeled as climate changes.

The use of unstructured grids and massive parallelization of code will see larger and more comprehensive forward and inverse models evolve over the next decade.

Summary

The ready availability of relatively cheap fast computers with graphic processing units (GPU’s) that lend themselves to massively parallel processing, combined with simulation code that is open-source and readily available, will hopefully lead to most undergraduate stratigraphy courses being based around forward and inverse stratigraphic modeling exercises where three-dimensional stratigraphic hypotheses can be numerically tested in real-time and the consequences of sea level change and the coastal response to changed wave and current environments will be more widely understood. A stratigraphy forecast will become as common as the weather forecast (but hopefully more reliable. . .).

Geology is on the cusp of a revolution in stratigraphic education and prediction that is reaching maturity after a 40-year gestation period.

Geometry of nature

Definition

The fractal geometry is a young branch of mathematics that studies the configuration of complex shapes and phenomena formed by the repetition of patterns.

Introduction

“Clouds are not spheres, mountains are not cones, coastlines are not circles, and bark is not smooth, nor does lightning travel in a straight line” (Mandelbrot 1982). The fractal geometry was developed by Benoît Mandelbrot in the 1970s to describe those and all other chaotic geometries observed in nature. The theory states that natural phenomena can be characterized as a repetition of self-similar (isotropic) or self-affine (anisotropic) patterns with dimensions, not limited to the Euclidean 1-, 2-, and 3-D planes. Thus, the complexity of fractal geometries is described by the so-called Fractal Dimensions (FDs), real numbers within the [1, 4] interval. This means that the more complex a line, a polygon, or a prism is, the higher to 1 (but lower than 2), 2 (but lower than 3), and 3 (but lower than 4) its dimension is, respectively.

Applications of the fractal geometry in science are nearly as many as natural phenomena exist. One example is the Remote Sensing (RS)-based investigation of scale dependencies of dynamic processes in vegetation, especially between individual leaves and the ecosystem. Since such dynamic processes are composed by nonlinear phenomena, the implementation of linear methods for its analysis might lead to local approaches with limited applicability beyond specific circumstances. The use of the fractal geometry, instead, can greatly contribute to RS of vegetation and help understanding image features as interconnected and scale-independent spatiotemporal patterns.

Fractal Geometry and the Power Law (PL) Distribution of Sun-Induced Chlorophyll Fluorescence (SIF)-Emitting Objects

Several approaches exist to mathematically prove the existence of fractal geometry in the distribution of RS-measured objects; the computation of universal Power Laws (PLs), also known as scaling laws, is one of them (Nagajothi et al. 2021). A PL distribution indicates the presence of fractal geometry composed by patterns where few occurrences of large magnitudes and numerous occurrences of small magnitudes are observed regardless the scale. The function of a PL distribution is described with the following equation:

$$y = \alpha x^\beta$$

where α is a constant representing the scale, and β is the exponent which represents the dimension of the function (closely related to the fractal dimension). Examples of PL distribution can be found almost in any area of research. For instance, in economics, a PL can describe how the richness in a country is distributed in few individuals holding huge amounts of money and many individuals with scarce monetary resources. Another example can be found in linguistics, where the frequency of words in a text follows a PL as well, with few words repeated thousands of times, and many words used only in few occasions.

Hypothetically, PLs can be used to describe the distribution of RS-measured properties of vegetation like the emitted SIF signal, since: (i) Its heterogeneity is related to spatial patterns defined by factors like canopy structure, shape, and size of agricultural fields or the organization of tree species in a forest; and (ii) SIF, as a red light emitted from vegetation, is more clearly aggregated across spatial scales (pixel sizes) than other more uniform signals like reflectance. Therefore, this chapter focusses on the analysis of the distribution of SIF emitting objects in an agricultural field to confirm whether they present a PL distribution (fractal geometry) or not, and

how the scaling and dimension factors behave across spatial scales.

Case Study: “Fractal Geometry for SIF-Downscaling”

Context: The world is confronted with substantial socioeconomic challenges. Agricultural production must ensure food security for a growing population, while it is imperative to protect and sustainably manage natural resources. Cropland expansion at the cost of natural ecosystems is not an option; therefore, large-scale farming must employ technology and advanced management to improve yields. RS offers possibilities to contribute making this possible. Recently available RS platforms equipped with SIF sensors constitute a powerful tool, since SIF shows large sensitivity to actual photosynthetic efficiency of crops (Mohammed et al. 2019). Such information is complementary to commonly used Vegetation Indices (VIs) and offers new pathways to assess plant health and, thus, optimize crop management. The forthcoming Fluorescence Explorer (FLEX) satellite mission of the European Space Agency (ESA) was planned within this context. Its relatively coarse resolution of 300 m, however, limits applicability for small field sizes and to investigate inter-field heterogeneity of croplands. Thus, downscaling satellite SIF products (understood as the increase of the spatial resolution) is currently a research subject of utmost importance.

Previous studies have addressed the SIF-downscaling considering its physical relation with explanatory variables like

the land surface temperature (Duveiller et al. 2020), and using machine learning-based statistical relations with VIs (Zhang et al. 2020). Another approach with applications on plant phenotyping was presented by Krämer et al. (2021), who analyzed the potential use of aggregated SIF pixel to extract representative values for crop plots representing few m^2 . Despite the great relevance of these contributions, a more versatile downscaling approach capable to run in a diversity of ecosystems is still not available but needed. We hypothesize that the flexibility of the fractal theory as a complexity measure together with the discontinuity of self-similar geometries captured in RS data (Sun et al. 2006) enables new strategies to advance downscaling approaches of SIF.

Aims: This study aims (i) to analyze if the aggregation of SIF over vegetation objects follows a universal PL distribution (i.e., representing fractal geometry) across spatial scales, and (ii) to evaluate how the scaling and dimension components of the PLs behave across spatial scales.

Analysis: We analyze the fractal geometry vegetation (SIF-emitting) objects through the computation of PLs at 1.5, 5, 10, and 15 m pixel^{-1} resolutions. Far red SIF at 740 nm (hereafter named “SIF”) in a 65 ha soybean field was retrieved from an imaging fluorometer (IBIS, Specim, Oulu Finland) with the Spectral Fitting Method (SFM, Cogliati et al. 2015; Fig. 1a). Only vegetation pixels were considered and afterward segmented into individual homogeneous objects through unsupervised classification (Fig. 1b). For the first aim, the total SIF (SIF_{TOT}) of each object was calculated and its distribution plotted in order to identify the presence of a PL distribution. For the second aim, the scaling

Fractal Geometry and the Downscaling of Sun-Induced Chlorophyll Fluorescence Imagery, Fig. 1 Sun-Induced chlorophyll Fluorescence (SIF) image (a) and the respective segmented images

considering individual aggregation scales, i.e., 1.5, 5, 10, and 15 m pixel^{-1} (b)

Fractal Geometry and the Downscaling of Sun-Induced Chlorophyll Fluorescence Imagery, Fig. 2 Power Law (PL) distributions of the total Sun-Induced chlorophyll Fluorescence (SIF_{TOT}) data observed

and dimension factors of the PLs from the different spatial resolutions were compared in order to understand if they follow scale-independent patterns.

Results: Besides the high intrafield variability observed in Fig. 1, the distribution of the SIF_{TOT} information aggregated by objects follows the PL distribution at all analyzed scales (Fig. 2a). Such order, characterized in the function equations, describes how the data is arranged in patterns of few occurrences of objects with high SIF_{TOT}, and numerous occurrences of objects with low SIF_{TOT} emission. For downscaling purposes, the information about known variables related to the analyzed feature, like the object area (Fig. 2b), could potentially be used to infer the SIF_{TOT} of the polygons. Furthermore, the linear increase of the scaling factor and the nearly constant dimension factor for 1.5 to 15 m pixel⁻¹ sizes (Fig. 2c) might indicate the scale-invariant property of the SIF signal aggregation patterns within the range of analyzed resolutions.

Summary

Our results indicate that the distribution of the SIF_{TOT} information aggregated by object follows the PL distribution for 1.5 to 15 m pixel⁻¹ resolutions, i.e., the fractal geometry is present in the distribution of individual SIF-emitting objects at all analyzed scales. Moreover, the linear ($R^2 = 0.998$) increase of the PL-scaling component, and the nearly constant dimension across the scales, might be an indicator of the scale-invariant property of the SIF signal aggregation patterns within the range of analyzed resolutions.

In theory, similar PL characterizations of high resolution SIF-explanatory variables could help to understand how to spatially disentangle SIF_{TOT} represented in a coarse pixel (e.g., measured by FLEX) in the SIF_{TOT} contributions of individual vegetation objects within the measurement footprint. Further studies might address that subject across diverse

ecosystems to provide more evidence on the suitability of this proposed approach to downscale and link coarse-scale-retrieved SIF_{TOT} with field-level SIF_{TOT} information.

Definition

A fractal is an object or feature characterized by its fractal dimension that differs from the integer Euclidian dimension of the space in which the fractal is imbedded. On the one hand, fractals are often closely associated with the random variables studied in mathematical statistics; on the other hand, they are connected with the concept of “chaos” that is an outcome of some types of nonlinear processes. Fractals are phenomena measured in terms of their presence or absence in boxes belonging to arrays superimposed on the domain of study in 1-D, 2-D, or 3-D space. Several phenomena that originally were thought to be fractals turned out to multifractals, which are “measures” representing of how much of a feature is present within the boxes used for measurement. Multifractals are spatially intertwined fractals.

Introduction

The word “fractal” was coined by Mandelbrot (1975). Evertsz and Mandelbrot (1992) explain that fractals are phenomena measured in terms of their presence or absence in boxes belonging to arrays superimposed on the domain of study in 1-D, 2-D, or 3-D space, whereas multifractals are either spatially intertwined fractals (*cf.* Stanley and Meakin 1988) or mixtures of fractals in spatially distinct line segments, areas, or volumes that are combined with one another. During the past 40 years, the fractal geometry of many natural features in Nature has become widely recognized (see, e.g., Mandelbrot 1983; Cheng 1994; Stoyan and Stoyan 1994, Turcotte 1997; Sagar et al. 2004, Carranza 2008; Ford and

Blenkinsop 2009; Agterberg 2012; Cheng 2006, 2008, 2012; Korvin 1992; Zuo and Wang 2016; Agterberg 2020). Fractals in geoscience either represent the end products of numerous, more or less independent, processes (e.g., coastlines and topography), or they result from nonlinear processes, many of which took place millions of years ago within the Earth’s crust. Although a great variety of fractals can be generated by relatively simple algorithms, theory needed to explain fractals of the second kind generally is not so simple, because previously neglected nonlinear terms have to be inserted into existing linear, deterministic equations (Lovejoy and Schertzer 2018).

Many geological features display random characteristics that can be modeled by adopting methods of mathematical statistics. A question to which new answers are being sought is: Where does the randomness in Nature come from? Nonlinear process modeling is providing new clues to answers. Spatial distribution of chemical elements in the Earth’s crust and features such as the Earth’s topography that traditionally were explained by using deterministic process models now also are modeled as fractals or as multifractals. Which processes have produced phenomena that are random and often characterized by non-Euclidian dimensions? The physico-chemical processes that have resulted in the Earth’s present configuration were essentially deterministic and “linear” but globally as well as locally they may display random features that can only be modeled by adopting a nonlinear approach that is increasingly successful in localized prediction. The situation is analogous to the relation between climate and weather. Longer-term climate change can be modeled deterministically, but short-term weather shows random characteristics that are best modeled by adopting a nonlinear approach in addition to the use of conventional deterministic equations.

This article reviews fractal modeling of solid Earth observations and processes with emphasis on topography, thickness measurements, geochemistry, and hydrothermal processes. There is significant overlap with multifractals that also will be discussed. Special attention is paid to improvements in goodness of fit and prediction obtained by nonlinear modeling. Some examples are as follows: The Pareto distribution is closely associated with fractal modeling of metal distribution within rocks or surficial cover in large regions. The concentration-area (C-A) method (Cheng et al. 1994) is a useful new tool for geochemical prospecting to help delineate subareas with anomalously high element concentration values that can be targets for further exploration involving drilling. Cheng (2016) has introduced the concept of fractal density that replaced ordinary density of substances with multifractal characteristics. The spatial distribution of ore deposits within large regions or within worldwide permissive tracts often is fractal or multifractal.

Two frequency distribution models frequently used in the mathematical geosciences are the lognormal and the Pareto.

The normal distribution that underlies much, especially early, theory of mathematical statistics can be regarded as a lognormal distribution with negligibly small coefficient of variation (ratio of mean and standard deviation). Both the lognormal and the Pareto are the so-called stable frequency distributions with generating processes that involve summations of random variables with different (usually unknown) frequency distributions. The Pareto applies to tails of frequency distributions only. Both types of frequency distribution often can be explained as the result of multifractal cascade-type modeling.

Fractal Dimension Estimation

Fractals can arise in chaotic situations. A famous example of chaos is Poincaré's (1899) study of the three-body problem in mechanics. Small differences in the initial conditions produce very great differences in the outcomes. Likewise, Lorentz (1963) discovered how miniscule changes in the initial state of a time series computer simulation experiment grew exponentially with time to yield results that did not resemble one another at all, although the equations controlling the process were the same in all experiments. The different outcomes orbited along a bounded region in 3-D space known as a chaotic attractor with fractal properties.

Fractals also may reflect self-similarity. Mandelbrot (1975) discovered that the increased detail of many different types of natural phenomena when they are studied at larger-scale maps or quantified with longer yardsticks often display self-similarity and can be quantified by estimating their fractal dimension. An example of self-similarity persistent across large areas is shown in Fig. 1 from Krige (1966). The two maps represent 2-D moving averages of gold inch-dwt values in the Klerksdorp goldfield in South Africa. In Fig. 1a, these averages were computed for overlapping square areas measuring 500 feet on a side; in Fig. 1b, the squares measured 10,000 feet on a side. Thus, each average value contoured in Fig. 1b was based on about 400 as many original values as the average contoured in Fig. 1a. Nevertheless, the resulting patterns are similar in appearance indicating self-similarity.

A second example of fractal dimension estimation is given in Figs. 2, 3, and 4. The perimeter of an object in two-dimensional space can be estimated by approximating the true perimeter by a sequence of straight-line segments (yardsticks or unit radii) as illustrated in Fig. 2. These segments have the same length except the last one in the sequence. In general, the estimated perimeter underestimates the true perimeter except when the line segments become infinitely short. Mandelbrot (1975) applied this method to measure the length of the coastline of Britain. A log-log plot

Fractal Geometry in Geosciences, Fig. 1 Gold inch-dwt trend surfaces in the Klerksdorp goldfield based on 2-dimensional moving averages for two areas with similar average gold grades. (a) Moving averages of 100 × 100 ft. areas within a mined-out section of 500 × 500 ft. (b) Moving averages of 2,000 × 2,000 ft. areas within mined-out section of

10,000 × 10,000 ft. Although the area covered in the case of (b) is 400 times as large as that in the case of (a), the resulting patterns are similar indicating scale-independence across large areas in this goldfield (Source: Krige 1966, Fig. 3)

of the measured length of coastline (y) against segment length (x) for segments greater than a critical limit value could be approximated by a straight line, $y = a + b \cdot x$. He defined the fractal dimension D as being equal to $2 - b$. For very short yardsticks, $b = 0$ and $D = 2$. A simple example of application of this approach to a geological map is to be shown in Figs. 3 and 4.

Fractal Geometry in Geosciences, Fig. 2 Measurement of the perimeter of a 2-dimensional object depicted on a geological map (Source: Agterberg 1980, Fig. 2)

Fractal Geometry in Geosciences, Fig. 3 Thirty-foot contour map of Sparky sandstone thickness in Lloydminster area, Alberta, mapped by Burnett and Adams (1977) (Source: Agterberg 1980, Fig. 3)

Figure 3 is a contour map of 30 feet (9.14 m) thickness of the oil-rich Sparky sandstone unit near Lloydminster, Alberta, originally constructed by Burnett and Adams (1977). In Agterberg (1980) the perimeters of these objects were measured using yardsticks of different lengths for the method explained in Fig. 1, with the results shown in Fig. 4 (Case 1). When the unit radius is set at 1.5 miles (2.4 km) or less, the measured perimeter provides a reasonably good approximation of the combined length of the contours in Fig. 3. However, for radii greater than 1.5, a shorter “perimeter” is measured. For yardsticks between 2 and 6 miles in length (Case 1 in Fig. 4), the measurements fall approximately on a straight line with slope equal to 0.66 from which it follows that $D \approx 1.34$. Yardsticks of 10 miles or longer were not used because then only few relatively large objects can be measured.

Burnett and Adams (1977) also published a more detailed Sparky sandstone thickness map for a much smaller subarea within the area of Fig. 3. For the objects shown in Fig. 2, this subarea gave $D \approx 1.38$. The more detailed thickness map (not shown here) gave $D \approx 1.34$ (Case 2 in Fig. 4). The difference between results for the subarea and the area of Fig. 2 is that shorter yardsticks could be used in Case 2, because the 30 ft. Sparky thickness contours are shown in much greater detail on this larger-scale map. Tentatively, it may be assumed that the degree of smoothing used for the smaller-scale map was the same as that for the larger-scale map on which more detail could be shown. The fractal dimension is independent of the degree of smoothing. This example also has been considered

Fractal Geometry in Geosciences, Fig. 4 “Perimeter” measured for 2-dimensional objects depicted in Fig. 3 by method illustrated in Fig. 2 (Case 1). Results for smaller subarea within the area of Fig. 2 are shown as Case 1a. Perimeters measured on a more detailed (larger scale) map are shown as Case 2. The three lines of best fit show similar slopes but results for smaller units of distance to measure perimeters on the larger scale map fit in with results for larger units of distance indicating scale independence (Source: Agterberg 1980, Fig. 7)

by Mandelbrot (1983). It illustrates that the principle of self-similarity can be applicable to geological maps produced at different scales. Self-similarity or independence of scale is a feature of multifractals as well.

An early success of fractal geometry in the geosciences was the modeling of Brownian landscapes by Mandelbrot (1977). Realistic representations of mountainous terrains with dimensions less than 3 and for elevation contours less than 2 were obtained in a variety of computer simulation experiments. Later, multifractal models also were used for the modeling of topography (Lovejoy and Schertzer 2007). These authors have reviewed the history of fractal geometry pointing out that, early on, several mathematicians and geophysicists had identified problems of differentiability and integrability in connection with some types of natural phenomena. For example, Perrin (1913) wrote: "Consider the difficulty in finding the tangent to a point of the coast of Brittany ... depending on the resolution of the map the tangent would change. The point is that a map is simply a conventional drawing in which each line has a tangent. On the contrary, an essential feature of the coast is that ... at each scale we guess the details which prohibit us from drawing a tangent." With respect to problems of integrability, Steinhaus (1954) stated: "The left bank of the Vistula when measured with increased precision would furnish lengths ten, hundred, or even a thousand times as great as the length read off a school map. A statement nearly adequate to reality would be to call most arcs encountered in nature as not rectifiable."

Among the early pioneers, Lovejoy and Schertzer (2007) list Vening Meinesz (1951) who argued that the power spectrum $P(k)$ of the Earth's topography has the scaling form $k^{-\beta}$ where k is a wave number ($= 2\pi \times$ frequency) and $\beta \approx 2$. Vening Meinesz (1951) originally based his scaling model on a development of the Earth's topography in terms of spherical harmonics up to the 16th order making a separation between continents and oceans. He showed that mean square elevation (y) is approximately related to order x of harmonic according to the power law relation $y = C \cdot x^{-\beta}$ where C and β are constants. Orders of spherical harmonics are analogous to wave numbers in a periodogram which is a commonly used tool in time series analysis. A multifractal series of values is characterized by a straight line on the log-log plot of its power spectrum (Agterberg 2014). Vening Meinesz (1964) refined his earlier analysis by development in spherical harmonics of the Earth's topography to the 31st order. His later curves suggest that β is slightly less than 2 for $n > 5$, although there may exist an increase in y for higher orders, especially for continental topography. Although the precise value of β is not known exactly, it is clear that the Earth's topography on the continents as well as on the ocean floor approximately displays the same type of fractal/multifractal behavior.

Separation of Geochemical Anomalies from Background by Fractal Methods

Cheng (1994) has studied the spatial distribution of 1030 concentration values of gold and associated elements in partially altered volcanic rocks in the Mitchell-Sulphurets area, northwestern British Columbia (Fig. 5a and b). A plot of Au content in surface samples from altered and unaltered rocks using logarithmic probability paper ($=$ lognormal $Q-Q$ plot, Fig. 5c) suggests that the gold concentration values satisfy a single, positively skewed frequency distribution that is approximately lognormal. The alteration pattern of Fig. 5b closely resembles the >200 ppb Au pattern of Fig. 6 showing a sequence of geochemical isopleths (isolines or contours for concentration values in ppb Au). In Fig. 5d, log-log paper is used to plot the cumulative area of surface rocks with larger concentration values against the contour value. The altered and unaltered rocks show two different power-law relations. This indicates that a power-law-based approach can be useful for the delineation of geochemical anomalies in addition to commonly used approaches directly based on element frequency distributions and contour maps (see, e.g., Sinclair 1991).

From the isopleths of Fig. 6, an optimum threshold for separating anomalies from background areas can be selected by means of the log-log plot for the element concentration-area relation shown in Fig. 5d. This threshold coincides with a sudden change in the rate of decrease of the area enclosed by higher value contours on the log-log plot. Suppose $A(\rho)$ denotes the area with concentration values greater than the contour value ρ . This implies that $A(\rho)$ is a decreasing function of ρ . If v represents the threshold, the following empirical model often provides a good fit to the data for different elements in the study area:

$$A(\rho \leq v) \propto \rho^{-\alpha_1}; A(\rho > v) \propto \rho^{-\alpha_2}$$

where $\propto$ denotes proportionality; α_1 and α_2 are different exponents.

Figure 7 is a log-log plot satisfying the preceding two power-law relations for Au. All areas were computed from separate contour maps such as those shown in Fig. 6. Pairs of estimated exponents and corresponding optimum thresholds for 28 elements or oxides were presented by Cheng (1994, Table 1). The thresholds delineate anomalous areas. Comparison of the areas above and below the threshold of 200 ppb Au on the contour map (Fig. 6) with the geological map (Fig. 5a) shows significant spatial correlation between the areas with Au concentration above 200 ppb and Au-associated alteration zones. This concentration-area plot approach (C-A model, cf. Cheng et al. 1994) has become widely used in geochemical exploration (Cheng 1999).

Fractal Geometry in Geosciences, Fig. 5 Mitchell-Sulphurets mineral district, northwestern British Columbia. Four plots originally constructed by Cheng (1994): (a) Simplified geology after R.V. Kirkham (personal information, 1993) including outline of alteration zones; (b) Sampling sites and (smoothed) isopleth for 200 ppb gold

concentration value; (c) Lognormal $Q-Q$ plot (Au terminations below 2 ppb detection limit are shown as horizontal line); (d) Log-log plot for area enclosed by isopleths (including circumference of pattern for 200 ppb in b). Straight lines are least-squares fits (log base: 10 in ppb) (Source: Cheng (1994), Fig. 3)

Fractal Perimeter-Area Relation

The following perimeter-area ($L-A$) relationship was introduced by Mandelbrot (1983) for similarly shaped sets: $L(\delta) = C \cdot \delta^{(1-D)} \sqrt{A(\delta)^D}$ where C is a constant. A modification of this equation was introduced by Cheng (1994) as follows (*cf.* Cheng et al. 1994). For yardstick δ , the estimated length and area

of a pattern in 2-D can be expressed as: $L(\delta) = L_0 \delta^{(1-D)}$; $A(\delta) = A_0 \delta^{(2-D)}$. Theoretically, for a group of similarly shaped sets, there exist power-law relationships between any two measures of area and perimeter. For example, two areas A_i and A_j enclosed by contours i and j are related to their perimeters L_i and L_j as follows:

Fractal Geometry in Geosciences, Fig. 6 Successive binary patterns for separate contours of Au, Mitchell-Sulphurets area (Source: Cheng et al. 1994, Fig. 5)

$$\frac{L_j(\delta)}{L_i(\delta)} = \left[\frac{A_j(\delta)}{A_i(\delta)} \right]^{D_{AL}/2}$$

where δ is the common yardstick used for measuring both areas and perimeters. The fractal dimension D_{AL} satisfies $D_{AL} = 2D_L / D_A$, where D_L and D_A denote fractal dimensions of perimeter and area, respectively. The contours for Au in Fig. 6 show similar shapes suggesting that the current perimeter-area modeling approach is valid.

Cheng (1994) subjected element concentration maps as shown for Au in Fig. 6 to perimeter-area analysis as follows. Experimental results for Au, Cu, and As are shown on log-log plots in Fig. 8 using perimeters and areas for different contours with concentration values above the previously defined threshold using the element concentration-area method (Fig. 5d for Au). There appear to be two different fractal dimensions in these diagrams on the right side of Fig. 8. The first of these (D_1) for yardsticks less than 300 m is equivalent to the so-called “textural” fractal dimension (Kaye 1989, p. 27). It is close to 1 for the elements considered and can be explained as the result of smoothing during interpolation. The other estimate of D_L (D_2) ranges from 1.14 to 1.33 and is probably representative of the true geometry of anomalous areas for the elements considered. It is noted that the least square estimates of D_1 and D_2 in Fig. 8 are subject to considerable uncertainty because they are based on relatively few points.

From any two of the three fractal dimensions (D_L) for perimeter, D_{AL} for perimeter-area relation, and D_A for area, the third one can be obtained by means of the relation $D_A = 2D_L / D_{AL}$. Theoretically, D_A cannot be greater than

Fractal Geometry in Geosciences, Fig. 7 Log-log plot representing the relationship between areas bounded by contours as shown in Fig. 6. Straight-line segments were fitted by least squares (Source: Cheng et al. 1994, Fig. 6)

2. In most applications of the perimeter-area method, it is set equal to 2 so that $D_L = D_{AL}$. The latter relation holds approximately true for Cu and As ($D_{AL} = 1.16$ and $D_A = 1.96$ for Cu and $D_{AL} = 1.28$ and $D_A = 2.07$ for As). For Au, the estimated value of D_{AL} (1.48) is significantly greater than the estimated structural fractal dimension (1.24). From the relation $D_A = 2D_L / D_{AL}$, it follows that $D_A = 1.68$ for gold which is less than 2. These results indicate that the distribution of Au in the alteration zones is more irregular than that of Cu or As.

The Multifractal Spectrum

Multifractals arose in physics and chemistry as a generalization of (mono)fractals (Meneveau and Sreenivasan 1987; Feder 1988; Lovejoy and Schertzer 2018). Multifractals can be regarded as spatially intertwined monofractals (Stanley and Meakin 1988). Mandelbrot (1989; see also Evertsz and Mandelbrot 1992) has emphasized that multifractals apply to continuous spatial variability patterns, whereas monofractals are for binary Yes-No type patterns. The relation between monofractals and multifractals also was considered by Herzfeld et al. (1995) who showed that the ocean floor could not be modeled as a monofractal. Better results were obtained by a multifractal model after incorporation of a nonstationary component (Herzfeld and Overbeck 1999). The multifractal spectrum is the tool par excellence in the study of multifractals. In this spectrum, a monofractal plots as a single spike because it has only one singularity associated with it. Examples of multifractal spectra for geoscience data

Fractal Geometry in Geosciences, Fig. 8 Relationships between perimeters and anomalous areas using contours with different values greater than thresholds for (a) Au, (c) Cu, and (e) As. Log-log plots on right side show relationships between estimated lengths of the perimeters

of the anomalous areas for (c) Au, (d) Cu and (f) As with variable yardstick. D1 and D2 are for textural and structural fractals dimensions, respectively. All solid lines were obtained by method of least square. (Source: Cheng et al. 1994, Fig. 8)

include Gonçalves et al. (2001), Pahani and Cheng (2004), and Arias et al. (2012).

A 1-D example of a multifractal is as follows. Suppose that $\mu = x \cdot \epsilon$ represents total amount of a metal for a line segment of length ϵ and x is the metal's concentration value. In the multifractal model, it is assumed that (1) $\mu \propto \epsilon^\alpha$ where $\propto$ denotes proportionality and α is the singularity exponent corresponding to x and (2) $N\alpha(\epsilon) \propto \epsilon^{-f(\alpha)}$ represents total number of line segments of length ϵ with concentration value x , and $f(\alpha)$ is the fractal dimension of these line segments.

There are three different ways in which a multifractal spectrum can be computed: histogram method, method of moments, and direct determination. The first two methods are described in Evertsz and Mandelbrot (1992). The histogram method is intuitively appealing because it is easy to understand. However, in practice it is better to use the method of moments with Legendre transform to be discussed here. This method produces better results faster than the histogram method although the latter can be useful in the study of frequency distributions of multifractals. The third method (direct determination) was developed by Chhabra and Jensen (1989).

Evertsz and Mandelbrot (1992) make a clear distinction between (1) Hölder exponent or singularity $\alpha(x) = \lim_{\epsilon \rightarrow 0} \frac{\log_\epsilon \mu\{B_\epsilon(x)\}}{\log_\epsilon \epsilon}$ at a point x and (2) "coarse" Hölder exponent $\alpha = \frac{\log_\epsilon \mu\{B_\epsilon(x)\}}{\log_\epsilon \epsilon}$ measured for a volume $B_\epsilon(x)$ around the point x . The mass partition function is: $\chi_q(\epsilon) = \sum_{N(\epsilon)} \mu_i^q = \int N_\epsilon(\alpha) (\epsilon^\alpha)^q dx$ with $N_\epsilon(\alpha) = \epsilon^{-f(\alpha)}$ where $f(\alpha)$ represents fractal dimension. It follows that $\lim_{\epsilon \rightarrow 0} \chi_q(\epsilon) = \int \epsilon^{q\alpha - f(\alpha)} d\alpha$ keeping in mind that $\alpha (= \alpha(q))$ also is a function of q . At the extremum, $\frac{\partial \{q\alpha - f(\alpha)\}}{\partial \alpha} = 0$ and $\frac{\delta f(\alpha)}{\delta q} = q$ for any moment q . Writing $\tau(q) = q\alpha - f(\alpha)$, it follows that $\frac{\delta \tau(q)}{\delta q} = q$. The multifractal spectrum satisfies $f(\alpha) = q\alpha - \tau(q)$. If the multifractal spectrum $f(\alpha)$ exists, the so-called codimension satisfies $C_1 = f(\alpha) - E$ where E is the Euclidian dimension (cf. Evertsz and Mandelbrot 1992).

In practice, a feature such as element concentration in rock samples is measured in blocks of different sizes. The mass partition function $\chi(\epsilon, q)$ then is the sum of all measurements raised to the power q for blocks with cell edge ϵ . Terms such as "mass partition function" were borrowed from physical chemistry (see, e.g., Evertsz and Mandelbrot 1992). The slopes of the lines on a log-log plot of partition function against size measure are estimates of the mass exponent $\tau(q)$. The singularity $\alpha(q)$ is the first derivative of $\tau(q)$ with respect to q , and the fractal dimension satisfies $f(\alpha) = q \cdot \alpha(q) - \tau(q)$.

A multifractal case history study in 2-D was provided by Cheng (1994) for gold in the Mitchell-Sulphurets area. The example of Fig. 9 shows how the multifractal spectrum was obtained for 100 ppb Au cutoff. Different grids with square

cells measuring ϵ on a side were superimposed on the study area. The average gold value was determined for each grid cell containing one or more samples with Au > 100 ppb. Each average value was raised to the power q . The sum of the powered values satisfies a straight-line relationship for any q in a multifractal model. This aspect is verified in Fig. 9a. The slopes of many best-fitting straight lines (including those in Fig. 9a) are shown as the function $\tau(q)$ in Fig. 9b. The first derivative of $\tau(q)$ with respect to q gives $\alpha(q)$, and the multifractal spectrum $f(\alpha)$ follows from the relation $f(\alpha) = q \cdot \alpha(q) - \tau(q)$ (solid lines in Fig. 9c and d).

The multifractal nature of the gold deposits in the Mitchell-Sulphurets area is shown in the spectra for different cutoff values in Fig. 9c and d. A fractal model would have resulted in a spectrum consisting of a single spike characterized by two constants: the fractal dimension $f(\alpha)$ and the singularity α . The four spectra of Fig. 9c and d are approximately equal on the left side, which is representative of the largest concentration values. The point where the multifractal spectrum reaches the α -axis and the slope of the curve at this point together determines the approximate area-concentration power-law relation on the right side in Fig. 9d (Agterberg et al. 1993; Cheng et al. 1994). The maximum value of $f(\alpha)$ in Fig. 9c and d decreases with increasing cutoff value. In general, if $f(\alpha) < 2$ in 2-D space, it can be assumed that the multifractal measure is defined on fractal support (cf. Feder 1988).

Singularity Analysis

Singularity analysis is a relatively simple method based on fractal geometry (cf. Cheng 2007; Cheng and Agterberg 2009). The following examples illustrate the advantages of this approach. Figure 10 is the Gejiu Mineral District example (Cheng and Agterberg 2009). This area of about 4000 km² contains 11 large tin deposits (shown as triangles in Fig. 10a). Several of these, including the Laochang and Kafang deposits, are tin-producing mines with copper extracted as a by-product. Eight of these occur in the eastern part of the area where there is considerable pollution related to mining. Cheng and Agterberg (2009) applied singularity analysis to data from 1,056 stream sediment samples collected as part of the Chinese regional geochemistry reconnaissance project (Xie et al. 1997).

Original sample locations were 2 km apart both in the north-south and east-west directions. Twelve of these sampling points (see Fig. 10b) were used, for example, to illustrate the calculations involved in singularity analysis. Only two of these examples are reproduced here in Fig. 11. Tin concentration values from within the same 26 × 26 km² cells each contain 169 sampling points. The singularities can be estimated by fitting straight lines on log-log plots of either the tin concentration value (x) versus ϵ using $x = c \cdot \epsilon^{-\alpha/2}$, or

Fractal Geometry in Geosciences, Fig. 9 Construction of multifractal spectrum of gold in Mitchell-Sulphurets mineral district (see Fig. 5). (a) $\chi(\epsilon)$ represents sum of gold values greater than 100 ppb averaged for cells and raised to the power q ; cell edge ϵ in km; log base 10; lowest sets of solid triangles and squares are for q equal to -7

0.45 and -9.15 , respectively. (b) Slopes $\tau(q)$ of best-fitting straight lines including those shown in a as function of q . (c and d) Multifractal spectra for four different cut-off values. It is noted that, contrary to a multifractal, a fractal is characterized by a single dimension that would have a spectrum consisting of a spike (Source: Agterberg 1995, Fig. 4)

amount of metal $\mu = x \cdot \epsilon^{-2}$ versus ϵ using $\mu = c \cdot \epsilon^{-\alpha}$. In Fig. 10d, both methods are yielded similar estimates of the singularity α . The resulting pattern shows a number of relatively small anomalies, some of them approximately coinciding with large tin deposits.

A moving average map (Fig. 11c) was constructed for the same stream sediment samples using weighted averages of the 169 tin concentration values in surrounding squares. The inverse squared distance was used for each weight. Like ordinary kriging or using another moving average method (cf. Figure 1), this method yields a generalized picture in

which local variability is smoothed out. The pattern of Fig. 11c shows pollution of water in streams related to mining in the eastern part of the Gejiu area instead of the localized anomalies in Fig. 11d that may provide clues on occurrences of large tin deposits that have not yet been discovered.

Another example of local singularity analysis is shown in Figs. 12 and 13 after Xiao et al. (2012) for Ag and Pb-Zn deposits in northwestern Zhejiang Province, China. The southeastern part of this study area is relatively poorly explored but stream sediment survey data were available for the entire study area. Local singularity analysis as used for tin

concentration values in 1000 stream sediment samples using inverse distance weighted moving average. Eight of 11 large tin deposits fall on large anomaly in eastern part of area that is due to environmental pollution related to mining. (d) Distribution of local tin singularities. Tin deposits tend to occur in places where local singularity is less than 2 (Source: Cheng and Agterberg 2009, Fig. 1)

in the Gejiu example was applied to lead in stream sediments in this other example clearly outlining potential new target areas for further exploration.

Model of de Wijs

Mandelbrot (1983) has pointed out that a model introduced by de Wijs (1951) was the first example of application of fractal geometry in geoscience. This model for metal concentration values in blocks of rock was originally developed as follows: Suppose any block with metal concentration model ζ is repeatedly divided into halves with concentration values $(1 + d)\zeta$ and $(1 - d)\zeta$ where d is the so-called coefficient of dispersion. Then, the frequency distribution for metal concentration values in increasingly smaller blocks satisfies the so-called negative binomial distribution that rapidly approaches lognormal form. If there are p subdivisions, the

log-binomial distribution of the $\binom{p}{K}$ concentration values of the resulting $n = 2^p$ blocks is

$$X(p, K) = \zeta \cdot (1 + d)^{p-K} (1 - d)^K$$

where K satisfies the binomial distribution with $\mu(K) = p/2$ and variance $\sigma^2(K) = p/4$ (cf. Agterberg 1974, p. 322). This log-binomial has mean $\mu(X) = \zeta$ and variance $\sigma^2(X)$ approaching to:

$$\sigma^2(X) = \frac{p}{4} \cdot \left[\ln \frac{1-d}{1+d} \right]^2$$

A two-dimensional example of application of the model of de Wijs is shown in Fig. 14 for $p = 14$ and $d = 0.4$ (from Agterberg 2007). Here, the overall mean value was set equal to 1 and the blocks were taken to be squares, and at each

Fractal Geometry in Geosciences, Fig. 11 Examples of estimation of local singularity at locations shown in Fig. 10b. Cell size is length of side of square cells with half-widths set equal to 1, 3, 5, ..., 13 km. Plots on left and right show relations between values of μ and ξ versus cell size, respectively. Value of μ is sum of tin concentration values in all $2 \text{ km} \times 2 \text{ km}$ cells contained within the larger cells centered on a location with value of $\xi = \mu/\epsilon^2$; base of logarithms is 10. Straight lines were fitted

by ordinary least squares method (log of value regressed on log of cell size); R^2 = multiple correlation coefficient squared. Typically, all seven points fall on the best-fitting straight line although small deviations do occur (e.g., second point at Location 2). Slopes of straight-lines on left provide estimates of local singularity α and those on the right are for $\alpha - 2$ (Source: Cheng and Agterberg 2009, Fig. 2)

iteration a square block was subdivided into 4 blocks with concentration values $(1-d)^2$, $(1-d) \cdot (1+d)$, $(1+d) \cdot (1-d)$, and $(1+d)^2$, respectively. Values greater than 4 were truncated to more clearly display most of the spatial variability. Later, Mandelbrot (1989) clarified that the model of de Wijs produces a multifractal instead of a monofractal. It offers a simple explanation for the widespread occurrence of lognormality.

Multifractal Spatial Correlation

De Wijs (1951) developed his original model on the basis of 118 zinc concentration values for 2-m channel samples from a drift in the Pulacayo Mine in Bolivia. This data set has been subjected to many different kinds of statistical analysis including Matheron (1962), Agterberg (1974), Cheng and

Agterberg (1996), Chen et al. (2007), Lovejoy and Schertzer (2007), and Cheng (2014). Several of these different applications are described in Agterberg (2014) which also includes good results obtained by means of Whittle (1962)'s 3-D correlogram method. Figure 15 shows the original data together with the results of a signal-plus-noise model, which is close to what would be obtained by kriging or cubic spline-curve fitting. These other techniques are basically different from the fractal-multifractal methods because they assume that the true values to be estimated are masked by white noise that is to be eliminated.

Cheng (1994; also see Cheng and Agterberg 1996) derived general equations for the spatial covariance, correlogram, and semi-variogram of any scale-independent multifractal including the model of de Wijs. This model is for sequences of adjoining blocks along a line. Experimentally, their

Fractal Geometry in Geosciences, Fig. 12 Geological map of northwestern Zhejiang Province, China (Source: Xiao et al. 2012, Fig. 1)

semi-variogram resembles Matheron's semi-variogram for infinitesimally small blocks. Extrapolation of the corresponding spatial covariance function to infinitesimally small blocks would yield infinitely large variance when h approaches zero. The autocorrelation function of a multi-fractal satisfies:

$$\rho_k(\epsilon) = \frac{C\epsilon^{\tau(2)-2}}{2\sigma^2(\epsilon)}[(k+1)^{\tau(2)+1} - 2k^{\tau(2)+1} + (k-1)^{\tau(2)+1}] - \frac{\xi^2}{\sigma^2(\epsilon)}$$

where C is a constant, ϵ represents length of line segment for which an average zinc concentration value is assumed to be representative, $\tau(2)$ is the second-order mass exponent, ξ represents overall mean concentration value, and $\sigma^2(\epsilon)$ is the variance of the zinc concentration values. The unit interval ϵ is

measured in the same direction as the lag distance h . The index $k = \frac{1}{2}h$ is an integer value.

The Pulacayo orebody provides an example. The most important parameter on which this approach is based is the second-order mass exponent $\tau(2)$. In this application, it is estimated as the slope of the straight line fitted by least squares in Fig. 16 with $\tau(2) = 0.979 \pm 0.019$. Estimation for the 118 Pulacayo zinc values using an ordinary least squares model with $\tau(2) = 0.979$ gave:

$$\hat{\rho}_k = 4.37[(k+1)^{1.979} - 2k^{1.979} + (k-1)^{1.979}] - 8.00$$

The semi-exponential autocorrelation previously used for smoothing the zinc values of Fig. 15 is shown as a broken line in Fig. 17 together with the autocorrelation coefficients (for

Fractal Geometry in Geosciences, Fig. 13 Raster map for Fig. 12 showing prospecting target areas for Ag and Pb-Zn deposits delineated by comprehensive singularity anomaly method (cell size is 2 km × 2 km). Known Ag and Pb-Zn deposits are indicated by stars (Source: Xiao et al. 2012, Fig. 13)

lag distance $h > 0$) to which it was fitted. Its “nugget effect” at the origin would explain about half of total variability of the zinc values. On the other hand, use of the multifractal correlogram (solid line in Fig. 17) shows a continuous increase of spatial correlation toward the origin. The method used for fitting the multifractal correlogram does not apply when the lag distance becomes very small ($h < 0.07$) in Fig. 17 so that the true white noise at the origin cannot be estimated by this method. By means of local singularity mapping, white noise can be estimated to represent only about 2% of total variability of the zinc values. It represents measurement error and strong decorrelation at microscopic scale.

Figure 18a and b show the multivariate semi-variogram that satisfies the equation: $\gamma_k(\epsilon) = \xi_2(\epsilon) \left[1 - \frac{1}{2} \left\{ (k+1)^{\tau(2)+1} - 2k^{\tau(2)+1} + (k-1)^{\tau(2)+1} \right\} \right]$ with $\tau(2) = 0.979$ and $\xi_2(\epsilon) = 391.49$ in comparison with experimental semi-variogram values estimated from the 118 Pulacayo zinc values using arithmetic and log-log scales, respectively. As shown by Cheng and Agterberg (1996, Eq. (23)), if $\tau(2)$ is only slightly less than 1, the preceding theoretical equation can be approximated by $\gamma_k(\epsilon) = -\xi_2(\epsilon) \cdot \epsilon^{\tau(2)-1} \log_e \left[\frac{1}{2} \{ \tau(2) + 1 \} \tau(2) k^{\tau(2)-1} \right]$. Figure 18c

Fractal Geometry in Geosciences, Fig. 14 Realization of model of de Wijs (in 2-D for $d = 0.4$ and $N = 14$). Overall average value is equal to 1. Values greater than 4 were truncated (Source: Agterberg 2007, Fig. 3)

shows the experimental semi-variogram values on a graph with logarithmic scale in the horizontal direction only. The straight line in Fig. 18c was fitted by least squares. This approximate semi-variogram model provides a good fit. It is almost exactly equal to the logarithmic semi-variogram originally obtained by Matheron (1962, p. 180; also see his Table 6.1) who expanded his version of the model of de Wijs incorporating the geometry of channel samples taken at regular distance along the Pulacayo mining drift.

The example of Figs. 16, 17, and 18 shows analogy with the approach taken in singularity analysis. In both approaches, the assumption that there is a nugget effect is replaced with the assumption that autocorrelation becomes stronger over very short distances instead of being reduced to zero. This fundamental difference in approach is discussed in more detail in Agterberg (2014).

Fractal/Multifractal Modeling of Point Patterns

Fractal and multifractal models can be used for pattern analysis of locations of mineral deposits on maps. Traditionally, two-dimensional point location distributions for mineral deposits were considered to satisfy classical statistical (primarily Poisson or negative binomial) distribution models with constant means and variances. However, evidence has been increasing that the means and variances depend on size of measurement area used for counting number of deposit points contained within it. Fractal and multifractal models both result in power-law relations between point density (number of points per unit of area) and size of study area. For fractal point patterns, the power-law exponent provides an estimate of the cluster dimension (*cf.* Feder 1988).

A different approach is needed to determine if a point pattern is multifractal instead of fractal. The purpose of this section is to present a simplified account of multifractal pattern analysis as it was first proposed by Cheng (1994). Later this novel approach was also published in Cheng and Agterberg (1995).

Suppose that A is a rectangular area in two-dimensional space with size $n \in_1 \times n \in_2$ where $\in_1 = k \in$ and $\in_2 = l \in$, with $\in$ being a unit distance. Consequently, A can be divided in $n \cdot m$ subareas $A_{ij} (\in_1, \in_2)$. The partition function of the number of points $N\{A_{ij} (\in_1, \in_2)\}$ within $A_{ij} (\in_1, \in_2)$ is

$$\chi_q(\epsilon_1, \epsilon_2) = \sum_{i=1}^n \sum_{j=1}^m [N\{A_{ij}(\epsilon_1, \epsilon_2)\}]^q$$

for $-\infty \leq q \leq \infty$. For multifractal $N\{A_{ij} (\in_1, \in_2)\}$, the partition function has a power-law relation with the cell sizes for any q , or

$$\chi_q(\epsilon_1, \epsilon_2) \propto \epsilon_1^{\tau_1(q)} \cdot \epsilon_2^{\tau_2(q)}$$

For a square cell with side $\in = \in_1 = \in_2$ ($k = l$), it follows that

$$\chi_q(\epsilon) \propto \epsilon^{\tau(q)}; \quad \tau(q) = \tau_1(q) + \tau_2(q)$$

The singularity exponent $\alpha(q)$ and multifractal spectrum $f(\alpha) = f\{\alpha(q)\}$ can be obtained successively by

$$\alpha(q) = \frac{d\tau(q)}{dq}; f(\alpha) = q\alpha(q) - \tau(q)$$

Setting $q = 2$, it follows that

$$E[N^2\{A_{ij}(\epsilon_1, \epsilon_2)\}] = c(k\epsilon)^{\tau_1(2)+1} (l\epsilon)^{\tau_2(2)+1}$$

where c is a constant and E denotes mathematical expectation. For an isotropic process

$$\tau_1(2) = \tau_2(2) = \tau(2)/2.$$

Point processes have been studied in spatial statistics (Ripley 1976; Diggle 1983; Cressie 1991; Stoyan and Stoyan 1994). Suppose x and y denote two points in the plane and $r = \|x-y\|$ represents the distance between them. The first-order intensity function (λ) and the second-order intensity function (λ_2) are used to describe isotropic, stationary point patterns. Although originally developed for patterns with an average point density that is independent of size of study area, the two intensity functions (λ and λ_2) can also be used for nonstationary multifractal point patterns. Diggle (1983) has defined the function $K(r) = \lambda^{-1} \cdot E$ (number of additional points within distance r from an arbitrary point). The expected number of additional points within distance r from an arbitrary point at 0 then satisfies

$$\lambda K(r) = 2\pi\lambda^{-1} \int_0^r \lambda_2(r) r dr$$

Conversely

$$\lambda_2(r) = \lambda^2 (2\pi r)^{-1} \frac{dK(r)}{dr}$$

The practical advantage of using $K(r)$ is that Ripley's

estimator (Ripley 1976; Diggle 1983) can be used to correct for edge effects that generally are strong in two-dimensional space. If r_{ij} represents the distance between two points labeled i and j within A , the edge effect corrected estimate of $K(r)$ satisfies

$$\hat{K}(r) = \frac{|A|}{N(A)^2} \sum_{i \neq j} w_{ij}^{-1} I_i(r_{ij})$$

where $I_r(r_{ij})$ is an indicator function that assumes the value 1 if $r_{ij} < r$; 0 otherwise. The weight w_{ij} represents the proportion of the circumference of the circle around point i with radius r_{ij} that lies within A . In Cheng and Agterberg (1995), it is shown that setting $r = k \in \sqrt{2}$ yields the approximate power-law relation

$$\lambda_2(r) \cong Cr^{\tau(2)-2}$$

where C is a constant. For sufficiently small ϵ

$$K(r) \cong C_2 r^{\tau(2)}; \quad C_2 = \left[\frac{|A|}{\mu(A)} \right]^2 \cdot \frac{2\pi C}{\tau(2)}.$$

Figure 19 shows the first geochemical exploration example to which the preceding technique was applied. It consisted of a set of 175 Au occurrences in an irregularly shaped area on the Iskut River map sheet (Minfile, Map 104B, 1989), north-western British Columbia (Cheng and Agterberg 1995). In order to use the multifractal model, cell sizes (ϵ) ranging from 3 to 20 km were used. Au occurrences were counted on eight gridded maps. Care was taken to account for edge effects. Figure 20a shows five plots of $\log \chi_q(\epsilon)$ versus $\log \epsilon$ with integer values of q ranging from 0 to 4, from which the experimental relationship between $\tau(q)$ and q , as well as $f(\alpha)$ against α were obtained (see Fig. 20b and c).

Fractal Geometry in Geosciences, Fig. 19 Gold mineral occurrences in Iskut River map sheet, northwestern British Columbia (from B.C. Minfile Map 104B, 1989) (Source: Cheng and Agterberg 1995, Fig. 4)

For example, three estimates of $\tau(q)$ accompanied by their 95% confidence intervals are $\hat{\tau}(0) = -1.34 \pm 0.15$, $\hat{\tau}(2) = 1.22 \pm 0.07$, and $\hat{\tau}(4) = 3.07 \pm 0.19$, respectively. As explained in Cheng and Agterberg (1995), the fractal model would have resulted in the following linear relationships:

$$\frac{\tau(q)}{q-1} = \frac{\tau(p)}{p-1}.$$

Consequently, for $q = 4$ and $p = 0$, the fractal model would have resulted in $\tau(4)/3 + \tau(0) = 0$. However, from the preceding considerations, it follows that $\hat{\tau}(4)/3 + \hat{\tau}(0) = 0.31 \pm 0.10 \neq 0$ proving that the Au occurrence point pattern is multifractal instead of monofractal. Further results for the example of Fig. 20 are shown in Fig. 21.

Another example of this approach described in Agterberg (2013, 2014) was based on occurrences of (1) volcanogenic massive sulfide (“Cyprus + Kuroko”) deposits, (2) porphyry copper deposits, and (3) podiform chromium deposits in many different “permissive tract” areas in the world (definitions and data according to Singer and Menzie 2010, Table 4.1). Deposit density (= number of deposits divided by permissive tract area) plotted against permissive tract area produces a linear pattern on the log-log plot for each of these three deposit types (*cf.* Singer and Menzie 2010, Fig. 4.5). Normally, one would expect deposit density to be independent of size of permissive tract area, and for stationary point processes the slopes of best-fitting lines on plots of this type would be zero. However, slopes of the three lines fitted by least squares are -0.62 (38 permissive tracts for massive sulfides), -0.63 (33 for porphyry coppers), and -0.53 (28 for chromium deposits), respectively. Singer and Menzie demonstrated that these estimated slopes are significantly different from zero pointing out that size of tract area can be used to predict deposit density. The correlation coefficients for these three linear associations (-0.801 , -0.788 , and -0.709 , respectively) are significantly less than zero. Agterberg (2013, 2014) assumed that the observed negative slope estimates could best be interpreted as estimates of $2 - D_c$ with D_c representing fractal cluster dimension. According to the statistical model described in this section, however, a multifractal explanation with $\hat{\tau}(2)$ values of 1.38 (volcanogenic massive sulfides), 1.39 (porphyry copper), and 1.47 (chromium deposits) provides a possible explanation as well.

Lognormal and Pareto Size-Frequency Distributions for Mineral Resources

The International Union of Geological Sciences has outlined actions required by the geoscience community pertaining to the comprehensive evaluation and future supply of mineral

Fractal Geometry in Geosciences, Fig. 20 Multifractal analysis results for Au mineral occurrences of Fig. 19. A, Log-log plot of mass-partition function for selected values of q , dots represent estimated values, solid lines obtained by LS fitting. B, $\tau(q)$ vs. q . C, Multifractal spectrum showing $f(\alpha)$ vs. α (Source: Cheng and Agterberg 1995, Fig. 5)

resources (Nickless et al. 2014). Such actions are required in the following three fields: (1) inventory, (2) statistical modeling of known resources, and (3) estimation of future resources. Patiño Douce (2016a, b, c, d) has published four important papers that are helpful in achieving these aims,

showing, for example, that for copper there would be a deficit of about 2.39×10^9 t (tons) by the end of this century if recent discovery rates are maintained. For comparison, according to the USGS Mineral Commodity Summaries (2015), proven copper reserves currently are 0.68×10^9 t. According to Patiño Douce (2016d), estimated copper resources are 2.32×10^9 t, whereas new demand by 2100 will probably be 4.70×10^9 t. Consequently, estimated future copper deficit is approximately equal to forward projected known copper resources. Using a different statistical method, this forecast was confirmed by Agterberg (2017b) who estimated copper resources to be discovered by the end of this century at 2.77×10^9 t with a 95% confidence interval of $\pm 0.994 \times 10^9$ that contains Patiño Douce's estimate.

Patiño Douce (2016b)'s paper is accompanied by a supplementary database with sizes and grades for 20 metals in thousands of known worldwide mineral deposits. For example, data for 2541 copper deposits were compiled from as many as 49 different sources. Patiño Douce (2016b) fitted lognormal distributions to the metal deposit size-frequency distributions in this data base pointing out that the logarithmic (base e) standard deviation ranges from about 2 to 3 for different metals, although average metal deposit sizes are greatly different. Later, both Patiño Douce (2016c) and Agterberg (2017a) showed that the largest deposits for different metals can be described by means of Pareto distributions. In the Pareto-lognormal metal size-frequency distribution model of Agterberg (2017a, b, 2018a, b, c, 2020), the lognormal has a Pareto upper tail separated from the central lognormal by a bridge zone. This model recognizes both (1) lognormality of metal content of ore deposits from within smaller regions and those belonging to different mineral deposit types (see, e.g., Singer and Menzie 2010) and (2) Pareto size-frequency distribution of the largest deposits but also for the smallest metal deposits that exhibit Pareto size-frequency distributions as well. For most metals, the size-frequency distributions are exceedingly skew. For example, the 50% of worldwide copper deposits with less than median size contain only 0.4% of all copper contained in the 2541 deposits while 60% of all copper is contained in the 2% largest deposits. Consequently, the tails of these size-frequency distributions can only be studied for very large samples.

The Pareto-lognormal model for metal deposits provides an alternative to other size-frequency distribution models, which until about 30 years ago almost exclusively were based on the lognormal model. However, as pointed out by Mandelbrot (1983, p. 263), oil and other natural resources have Pareto distributions and "this finding disagrees with the dominant opinion, that the quantities in question are lognormally distributed. This difference is extremely significant, the reserves being much higher under the hyperbolic than under the lognormal law." Pareto size-frequency distribution

modeling of the largest deposits has been used by many authors including Drew et al. (1982) and Crovelli (1995) for oil and gas fields and Turcotte (1997) for metal deposits. Like the lognormal, the Pareto-lognormal distribution is not universally applicable to all elements, several of which show bimodal or multimodal size-frequency distributions (Fig. 21).

The cumulative frequency distribution for the Pareto-lognormal distribution $F(x) = F(\log x)$ can be written as

$$F(\log x) \approx \Phi\left(\frac{\log x - \mu}{\sigma}\right) + H(\log x - \mu) \cdot B_1(\log x) \cdot (\log x - \mu)^{-\alpha} + H(\mu - \log x) \cdot B_2(\log x) \cdot (\mu - \log x)^{-\kappa}$$

where $\Phi\left(\frac{\log x - \mu}{\sigma}\right)$ represents the basic lognormal (logs base 10). $H(\dots)$ is the Heaviside function that applies to two filtered Pareto distributions, for positive and negative values

Fractal Geometry in Geosciences, Fig. 21 Spatial statistics for Au mineral occurrences. A. Log-log plot of relationship between $K(r)$ and distance r ; solid lines are LS fits for $\tau(2) = 1.219 \pm 0.037$. B. Log-log plot for relationship between second-order intensity λ_2 and r with theoretical line for $\tau(2) = 1.219$ (Source: Cheng and Agterberg 1995, Fig. 7)

of $(\log x - \mu)$, respectively; it signifies that values at the other side of μ are set equal to zero when this equation is applied to either the upper tail or the lower tail of the Pareto-lognormal distribution. The bridge functions $B_1(\log x)$ and $B_2(\log x)$ span relatively short intervals between the basic lognormal and the Pareto distributions for the largest and smallest values, respectively. They satisfy $\lim_{x \rightarrow \infty} B_1(\log x) = \lim_{x \rightarrow 0} B_2(\log x) = 1$ and $\lim_{x \rightarrow 0} B_1(\log x) = \lim_{x \rightarrow \infty} B_2(\log x) = 0$.

The Pareto-lognormal probability density function $f(\log x)$ corresponding to $F(\log x)$ can be written as

$$f(\log x) \approx \varphi\left(\frac{\log x - \mu}{\sigma}\right) + H(\log x - \mu) \cdot B_1(\log x) \cdot (\log x - \mu)^{-\alpha-1} + H(\mu - \log x) \cdot B_2(\log x) \cdot (\mu - \log x)^{-\kappa-1}$$

It may be useful for prediction of resources to be discovered in the future. The exponents in $(\log x - \mu)^{-\alpha-1}$ and $(\mu - \log x)^{-\kappa-1}$ reflect the fact that the Pareto probability density function remains linear on a plot with logarithmic scales for frequency and deposit size but has a steeper dip than in the corresponding plot for the cumulative frequency distribution.

Figure 22 (from Agterberg 2018b) shows lognormal plots for the worldwide size-frequency distributions of six metals. A lognormal distribution would plot as a straight line on a plot of this type. In each case, two types of departure from lognormality are indicated. There are fewer than expected lognormal frequencies for the largest deposits and more than expected lognormal frequencies for the smallest deposits. A Pareto distribution of the largest deposits has the property that it plots as a straight line on a log-log plot of rank versus size. Figure 23 (also from Agterberg 2018b) shows that the six metals taken, for example, have Pareto upper tails. The method used for fitting these Pareto's is a modification of Quandt (1966)'s least squares method. In this modification the very few largest deposits are not included for estimation because they tend to distort the shape of Pareto distribution (see Agterberg 2018a).

Figure 24 (from Agterberg 2020) shows the Pareto-lognormal distribution for copper together with the observed frequencies as a $Q-Q$ plot (Fig. 24a) and as a log-log plot of cumulative frequency versus copper deposit size (Fig. 24b). It clarifies that relatively many large copper deposits with sizes less than those in the upper Pareto tail are missing. The other departure is that there are more deposits in the lower tail than expected for the central lognormal distribution. An explanation for these two departures from lognormality is that (a) only the very largest deposits in the upper Pareto tail

were discovered and mined because of their stronger geophysical signals during exploration and their greater economic significance and (b) before the nineteenth century only relatively small orebodies could be mined causing a relative increase of frequencies of small and very small deposits in the metal size-frequency distributions. The current model does not only apply to worldwide metal size-frequency distributions but also to Canadian ones (Agterberg 2020) although the land mass in Canada covers only 6.6% of the world's continents.

The current Pareto-lognormal was based on the so-called double Pareto-lognormal model originally developed by Reed (2003) and Reed and Jorgensen (2003) with cumulative distribution function:

$$F(\log x) \approx \Phi\left(\frac{\log x - \mu}{\sigma}\right) - \frac{1}{\alpha + \beta} \left[\beta \cdot x^{-\alpha} A(\alpha, \mu, \sigma) \Phi\left(\frac{\log x - \mu - \alpha\sigma^2}{\sigma}\right) + \alpha \cdot x^{\beta} A(-\beta, \mu, \sigma) \Phi\left(\frac{\log x - \mu + \beta\sigma^2}{\sigma}\right) \right]$$

where $A(\vartheta, \sigma, \mu) = \exp.(\vartheta \mu + \vartheta^2 \sigma^2 / 2)$. This model has had various applications in the economic and actuarial sciences (Kleiber and Kotz 2003). The original Reed-Jorgensen model could not be applied to the worldwide or Canadian metal size-frequency model because of the departures from lognormality (a) and (b) mentioned in the preceding paragraph. One of the properties of Reed's double Pareto-lognormal model is that $\beta > 1$ but in all applications to metal size-frequency distribution κ (used as upper tail Pareto parameter instead of β) is significantly less than 1. It is possible that Reed's model is valid for world or large region metal size-frequency distribution but at present it is not possible to estimate β .

Summary

After their invention by Mandelbrot some 50 years ago, fractals with non-Euclidean dimensions have become widely applied in the geological and other sciences. In this entry, the focus has been on methods to estimate the fractal dimension or multifractal spectrum of geoscientific patterns. New approaches based on fractal geometry include the description of shapes of geological entities and the separation between anomalies and background in geochemistry. Singularity analysis uses local multifractal patterns of change in geological environments. The lognormal and Pareto frequency distributions of geological features including the sizes of mineral deposits can be based on fractal geometry in geoscience.

Fractal Geometry in Geosciences, Fig. 22 Lognormal $Q-Q$ plots for six metals. Sample sizes were 2541 (Cu), 1476 (Zn), 1102 (Pb), 464 (Ni) and 343 (Mo). In each case, frequencies for the largest and smallest deposits deviate from the straight-line patterns indicating lower

and higher number frequencies than expected on the basis of the lognormal size-frequency distribution models represented by the straight lines (Source: Agterberg 2018b, Fig. 26.2)

Fractal Geometry in Geosciences, Fig. 23 Sets of log (metal deposit size) values corresponding to estimates of upper tail Pareto coefficients (α) for the six metals of Fig. 22. Corresponding Pareto distributions are

shown as straight lines fitted by least squares method (Source: Agterberg 2018b, Fig. 26.4)

Fractal Geometry in Geosciences, Fig. 24 Two types of plots for worldwide copper deposits. Red lines are for Pareto-lognormal frequency distributions showing good fit to the data in the $Q-Q$ plot of Fig. 22 for copper. Blue lines correspond to straight line shown in Fig. 22a (Source: Agterberg 2020, Fig. 3)

Other developments along the line of multifractals and singularity are referred to other chapters of the current book.

Fractal Landscape

Ramendra Sahoo

Department of Earth and Climate Science, IISER Pune, Pune, India

Definition

Fractals are objects with scale-invariant geometry, introduced to describe the non-Euclidian shape of natural phenomena. Fractal dimension, which is proportionate to the degree of space filled by an object withing its embedding space, is generally used to describe the fractal geometry of natural landscapes. Multifractal geometry results, if we have heterogeneity of space filling across the embedding space. Fractal properties of landscape can often be quantitatively related to the spatio-temporal scale of the associated governing natural processes, which provides novel insights into the nonlinear dynamics ubiquitous in nature.

Introduction

Many natural phenomena look similarly complex under different resolutions, a property known as scale-invariance (not to be confused with scale-independence). Without an object with a representative dimension, often referred to as a scale in the geological literature, it is impossible to determine whether the object in a picture covers a few cm or km (e.g., a self-similar fold or a river network). These kinds of scale-invariant patterns are not characterizable with the help of a single scale. It was in this context that Mandelbrot (1967) introduced the concept of fractals in order to describe the complex geometry of a rocky coastline. Subsequently, many natural patterns and processes have been proven to be efficiently modeled by fractals. They include coastline and mountain topography (e.g., Mandelbrot 1982), river networks (e.g., Tarboton et al. 1988), seismicity (e.g., Turcotte 1989), and ocean-floor bathymetry (e.g., Mareschal 1989), just to name a few. The fractal geometry of these natural phenomena can be described with fractal dimension, a number that agrees with our intuitive notion of dimension but need not be an integer.

Fractal dimension of any natural object also highlights the inherent dominant frequency present in its physical attributes. That dominant frequency, in turn, can be attributed to the scale (spatial and/or temporal) of the governing natural processes. For example, fractal dimension of sea level change time series can be related to temporal scale of climate pattern (Indira et al. 1996). Fractal characteristics of climate time series have also been used to find out the periodicity of climate pattern (Gipp 2001) and possible role of chaos in

climate dynamics. Geomorphologists have also related the fractal dimension of the topography to governing controls, such as tectonics, climate, and lithology (Liucci and Melleli 2017). Hence, the application of fractal concepts in natural science is providing novel insights into the underlying process dynamics. This entry focuses on the advancements and applications, along with a brief review, of the concepts of fractal and scaling in the field of geomorphology.

A Review of Fractals: A Unifying Basis to Describe Nature's Complexity

Scale-invariance is a fundamental property of fractal geometry. These geometries cannot be characterized by a single scale. For example, if we consider the famous problem of measuring the length of a coastline, its length keeps on changing with scale. Fractal dimension (d_f) is one of the ways to describe the geometry of such objects. If we define the embedding dimension (d_E) as the minimum Euclidean dimension required to contain the object, the volume $V(\delta)$ of an object can be measured by covering it with $N(\delta)$ balls of linear size δ , and volume δ^{d_E} . So,

$$V(\delta) = N(\delta)\delta^{d_E} \quad (1)$$

One might expect $N(\delta)$ scales as δ^{-d_E} , i.e., $N(\delta) \sim \delta^{-d_E}$ as the volume of the object doesn't change with change in scale. For a fractal object, we have

$$N(\delta) \sim \delta^{-d_f} \quad (2)$$

$d_f < d_E$ becomes an important norm to define an object as fractal (Mandelbrot 1982). The above expression can be rearranged as follows to give us an expression for fractal dimension.

$$d_f = \lim_{\delta \rightarrow 0} \frac{\ln N(\delta)}{\ln(1/\delta)} \quad (3)$$

We can use Eq. 3 to estimate the fractal dimension of any natural object (random or statistical fractals). For the same example of coastline length, we can measure the total length, $\delta N(\delta) = \delta^{1-d_f}$, and we would find that it increases as δ decreases. If we plot $N(\delta)$ as a function of δ on a log-log plot, we will get a straight line, whose slope will give an estimate of the fractal dimension of the coastline.

Self-similar Fractals

The scale-invariance nature of fractal objects can be dichotomized into self-similar and self-affine fractals. A self-similar fractal object constitutes of parts that can be rescaled

Fractal Landscape, Fig. 1 Construction of the Cantor set, by repeated removal of the middle third of each interval. The last row depicts a random Cantor set, where the segments are removed from each interval from the previous step ($n = 3$) at random, giving rise to a clumped

isotopically to match the geometry of the original object. Cantor set is a theoretical example of a self-similar fractal, and a drainage network is a natural example for the same. Let us consider the example of a regular deterministic Cantor set (Fig. 1). We start with a line segment of unit length, divide it into three parts, and finally remove the central part. After a number of iterations, the geometry converges to a set of points, known as Cantor set. At stage n of the construction, the set constitutes $N(\delta_n) = 2^n$ intervals of length $\delta_n = 3^{-n}$. The number of segments required to cover the total length is then given by

$$N(\delta_n) = \delta_n^{-d_f} \quad (4)$$

Equation 4 is similar to Eq. 2, and thus, we can use Eq. 3 to calculate the fractal dimension of the Cantor set.

Unlike the mathematical fractals, natural objects do not display exact self-similarity. Instead, they show some degree of statistical self-similarity over a limited spatial or temporal scale. Statistical self-similarity refers to scale-related repetitions of overall complexity but not of the exact pattern. We also observe step-like transition in the power-law relation (Eq. 4), where the environmental properties or constraints in the natural system may significantly change. Hence, the prevalence of power law with respect to the scale of observation within a certain range is commonly used to discern a fractal and, in that range, we can use Eq. 3 to calculate the fractal dimension.

Self-affine Fractals

Fractal objects that need to be rescaled anisotropically are classified as self-affine objects. Fraction Brownian motion (fBm) is a theoretical example of self-affine fractal, while earth's topography is a natural example having self-affine fractal geometry. These fractals can be described using a single-valued self-affine function, $h(x)$, which scales as follows:

distribution. Notably, the last two rows ($n = 4$) have same fractal dimension ($\ln 2 / \ln 3$); however, they are characterized by different set of lacunarity

$$h(x) \sim b^{-H} h(bx) \quad (5)$$

where H is called the Hurst exponent and provides a quantitative measurement of the roughness of the function $h(x)$. Eq. 5 explains that if we scale the function with a factor b horizontally ($x \rightarrow bx$), it must be scaled with a factor b^H vertically ($h \rightarrow b^H h$) in order that the resulting function overlaps the original function. For the special case $H = 1$, the transformation is isotropic and the system is self-similar. Using the roughness exponent, we also may further define a fractal dimension for the self-affine function using the following expression (Seuront 2009):

$$d_f = d_E - H \quad (6)$$

One corollary of the scaling relation of the self-affine function (Eq. 5) is

$$\Delta(\delta) \sim \delta^H \quad (7)$$

where $\Delta(\delta) = |h(x_1) - h(x_2)|$, for $\delta = |x_1 - x_2|$. For a self-affine function similar to Brownian motion, the standard deviation is defined as

$$\left\langle [h(x_1) - h(x_2)]^2 \right\rangle^{1/2} \sim |x_1 - x_2|^{1/2} \quad (8)$$

Equation 8 is similar to Eq. 7, giving $H = 1/2$. Consequently, the fractal dimension of a two-dimensional $h(x)$ is 1.5. In general, it is possible to generate a function, such as fractional Brownian motion, where the standard deviation scales in a more general manner as follows:

$$\left\langle [h(x_1) - h(x_2)]^2 \right\rangle^{1/2} \sim |x_1 - x_2|^H \quad (9)$$

While $H = 0.5$ recovers a Brownian motion, where direction of displacements is equally likely at each step, for

$H > 0.5$ and $H < 0.5$, the increments are positively (persistent) and negatively (antipersistent) correlated, respectively. Persistence and anti-persistence provide an intuitive sense of the governing physical processes of the natural system, such as climate dynamics (Xu et al. 2017).

Multifractals

Previous sections establish that natural patterns are adequately described by fractal geometry and fractal dimension irrespective of the measurement scale. Nevertheless, many natural phenomena are characterized by highly intermittent patterns (a few hotspots dispersed over a wide range of low-density areas). Mandelbrot (1982) recognized that objects with identical fractal dimension (e.g., deterministic and random Cantor set in Fig. 1) can have greatly different appearances owing to the spatial distribution of the gaps. Hence, he introduced lacunarity index, which uses higher order moments of height-height distribution to uniquely describe objects with intermittent patterns. The utilization of higher order moments was subsequently generalized through the concept of multifractals.

Multifractals are defined as union of subsets with different scaling factors. Morphologically, a multifractal object is described as having a spatially heterogeneous roughness exponent. The concept gets more intuitive if one thinks of fractal dimension in terms of probability of an object filling up its embedding space (analogous to counting the fraction of embedding space occupied by an object). A probability distribution can be completely defined by its moments. In case of multifractals, characterized by non-Gaussian underlying distribution, we need multiple moments to exhaustively describe their pattern. This can be achieved using the q^{th} -order structure functions that are an empirical generalization to higher orders of moments. We can define the q^{th} -order moment of the probability distribution, also known as the partition function (Halsey et al. 1986), as follows:

$$M_q(\delta) = \sum_{i=1}^{N(\delta)} f_i(\delta)^q \quad (10)$$

where $f_i(\delta)$ denotes the probability of finding the object in the segment i with a linear dimension δ , and $N(\delta)$ is the number of discrete segments. The generalized information dimension and the generalized correlation dimension are then expressed as (Seuront 2009)

$$I_q(\delta) = \frac{1}{q-1} \ln M_q \quad (11)$$

$$D(q) = \lim_{\delta \rightarrow 0} \frac{I_q(\delta)}{\ln(1/\delta)} \quad (12)$$

This generalized correlation dimension, $D(q)$, is defined for all real values of $q (\neq 1)$ and is estimated as the slope of the log-log plot of $I_q(\delta)$ vs δ . For $q = 1$, the generalized dimension is given by

$$D(q) = \lim_{\delta \rightarrow 0} \frac{1}{q-1} \frac{\ln \sum_{i=1}^{N(\delta)} f_i(\delta) \ln f_i(\delta)}{\ln(1/\delta)} \quad (13)$$

The set of points $(q, D(q))$ defines a curve that depicts the generalized spectrum of the measure $f(\delta)$. This spectrum is a decreasing function of q with a sigmoidal shape for a multifractal object. The partition function, $M_q(\delta)$, can also be expressed as a power-function of length scale as follows (Seuront 2009):

$$M_q(\delta) \propto \delta^{-\tau(q)} \quad (14)$$

where $\tau(q)$ is defined as a mass exponent function, which is linear for a monofractal object, that is, $\tau(q) = qH - 1$. For a multifractal object, if we combine Eqs. 11, 12, and 14, we get the following functional form for the mass exponent.

$$\tau(q) = (q-1)D(q) \quad (15)$$

The characterization of the measure $f(\delta)$ can also be done in terms of its multifractal spectrum, $f(\alpha)$, which is related to the mass exponent through a Legendre transformation (Evertsz and Mandelbrot 1992) as follows:

$$\alpha(q) = \frac{d\tau(q)}{dq} \quad (16)$$

$$f(\alpha(q)) = q\alpha(q) - \tau(q) \quad (17)$$

where $\alpha(q)$ is the local Holder's exponent. $\Delta\alpha$ is widely used in the literature as a measure of multifractality (e.g., Dutta 2017).

Scaling of Earth's Landscape

The shape of Earth's landscape is determined by numerous competing processes that act to either roughen or smoothen the surface. Fractal analysis provides a scale-independent robust measure of roughness observed in natural landscape. This section succinctly describes a few applications of fractal and multifractal concepts in the field of geomorphology.

Vening Meinesz (1951) was the first quantitative analysis of scaling in landscape topography and showed that the power spectrum $E(k)$ of topography (where k is a wavenumber) roughly scales as $k^{-\beta}$ with a spectral exponent $\beta \approx 2$. Later

results from subsequent bathymetric studies reported a range of values for the exponent ($\beta \sim 1.6\text{--}2.3$) across a wide range of scales. Accordingly, the isolines (intersection of topography with a horizontal plane, such as coastlines and contour lines) can also be characterized by power-law spectrum. Richardson (1961) found that the length of various coastlines varies in a power-law way with the length of the rulers used to measure them. Mandelbrot (1967) interpreted these scaling exponents in terms of fractal dimensions. Subsequently, fractal geometry (Mandelbrot 1982) has been proven to be a successful mathematical model for describing real landscapes. Fractal parameters, particularly the fractal dimension (FD), have been shown to be a good morphometric descriptor across the domains of geomorphology.

Surface roughness not only aids in characterization of landscape texture, but also is an important parameter in the evolution of landscape topography. This fact has led to an in-depth process-response investigation and association between the fractal nature of the topography and the governing controls in fluvial landscapes (e.g., Sahoo et al., 2020), fractal analysis of ice sheet surface and isolines (e.g., Rezvanbehbahani et al., 2019), and fractal analyses of coastal (Donadio et al., 2020) and aeolian landscape (Zgheib et al., 2018).

The fractal properties of natural surfaces (and thus their FD) change with the scaling range. A single FD may not be a good descriptor of terrain complexity for a large study area. Lovejoy and Schertzer (1990) argued that we need multifractal measures (rather than a unique scaling exponent, such as the FD) to describe any natural surface. A similar line of discussion arises in the analyses of fractures and other artificial surfaces (e.g., Morel et al., 2002). Multifractalism also aided in inferring process complexity based on the values of Holder's exponent (α) and generalized fractal dimension spectrum (D_q) of the topography (e.g., Dutta, 2017).

Drainage networks exhibit different drainage patterns depending on the hydrogeological properties of the underlying materials. First scaling relations for the drainage network patterns were proposed by Horton (1945) and Strahler (1957). Subsequent research on these scaling properties led geologists and hydrologists to the recognition of the fractal and multifractal nature of drainage networks (e.g., Tarboton et al. 1988; Camara et al., 2016). Indeed, the ubiquity of scaling relations in surface hydrology would be difficult to comprehend without wide range scale-invariance of the topography.

These scaling laws have been found to be valid for the topography and drainage networks of other planets as well (e.g., Gou et al., 2019). This undeniably shows the universality of the fractal nature of landscape geometry and establishes the fractal dimension (or set of scaling exponents in case of multifractal) to be a fundamental scale-independent property of the landscape.

Proposed Dynamical Models for Fractal Landscapes

Beyond describing the non-Euclidian shape of natural objects, fractal geometry also demands that we look into the possible process dynamics responsible for such forms of natural landscapes. This section describes a few interesting mathematical concepts proposed for the fractal nature of fluvial landscapes.

A geometry of landscape is fractal if there is no characteristic length scale. Ergo, one would expect the landscaping processes also to be devoid of any characteristic length. Fluvial landscapes, in particular bedrock rivers, are primarily dictated by hillslope smoothing (a diffusive process) and channel erosion (an advective process) (Tucker and Hancock 2010). The advection and diffusion processes operate at different timescales, which are defined as follows (Perron et al. 2008):

$$T_{adv} = \frac{L^{1-2m}}{K} \quad (18)$$

$$T_{dif} = \frac{L^2}{\kappa} \quad (19)$$

where L is the length scale of a landscape, and K and κ are channel erodibility and hillslope diffusivity, respectively. It is quite apparent from Eqs. 18 and 19 that diffusion process is scale-dependent, while the advection process is scale-independent for $m = 0.5$, which is an acceptable value for the exponent (Whipple and Tucker 1999). This is in good agreement with the observation in real topography (Pelletier 2004), where at large length scales, the model is self-affine and closely follows the power-law dependence and at smaller length scales, where hillslope processes are prevalent, the power spectrum drops off below the power-law trend. Channel erosion, therefore, is regarded as the primary surface process to produce fractal topography.

Another model proposed in the literature are Kardar-Parisi-Zhang (KPZ) equation, combining linear diffusion (for hillslope process) and nonlinear advection (for channel erosion) (Pelletier 2007; Duclut and Delamotte 2017).

$$\frac{\partial h}{\partial t} = \kappa \frac{\partial^2 h}{\partial x^2} + \frac{\lambda}{2} \left(\frac{\partial h}{\partial x} \right)^2 + \eta(x, y, t) \quad (20)$$

The first term on the right-hand side is the linear diffusion term. The second term is the nonlinear advection term and the third term is a random noise. KPZ equation in 3D generates a self-affine fractal surface under the combined action of smoothing by the diffusion and roughening by the nonlinear advection and the random noise. A deterministic KPZ model could also capture the drainage migration process (Pelletier

2007), which is credited as a major contributor to the dynamic complexity of the landscape (Chin 2002).

Other models suggested for the fractal nature of landscapes include diffusion limited aggregation (DLA) model, which has been proposed for generation of self-similar network pattern in dendritic rivers (Ossadnik 1992). DLA clusters have also been found to strongly resemble other natural network patterns, such as fault and joint network (Sornette et al., 1990) and mineral growth pattern (Fowler 1995). Least energy dissipation principle is another concept which has also been put forth as a possible mechanism for fractal structures of river network (Rodriguez-Iturbe et al. 1992).

A broad class of nonlinear physical problems, primarily consisting of complex geological processes or self-organized critical behavior, also invariably yields fractal behavior for natural landscape (Phillips, 2016). Nonlinearity in a dynamical system primarily arises from self-organized criticality or complexity. Multiple geomorphic controls and their associated dynamics give rise to complex geomorphic systems (e.g., Keiler, 2011). When there exists a strong feedback between the geomorphic components, such as climate-tectonics feedback (Molnar and England 1990), the dynamical system can move toward a chaotic state, giving rise to strange attractor with fractal scaling (e.g., Baas 2002). Conversely, a dominant effect of any autogenic control, such as lithology or catchment shape, in landscape evolution can result in a self-organized critical system (e.g., Phillips, 2016). In such scenarios, the system always evolves toward a finite number of critically stable state(s) and is primarily controlled by some form of threshold. Recent experimental or field-based studies also drew attention to the self-organized critical nature of fluvial geomorphic systems (e.g., Baynes et al., 2018). Resulting nonlinearity in fluvial landscapes can lead to complex behavior only at one scale or across multiple scales, and generation of fractal patterns with single or multiple scaling exponents.

Conclusion

Fractal concepts provide important tools to study the rough, crenulated, and crumpled 3-D surface of natural landscapes. Owing to its scale-independent property, fractal dimension captures the intricate complexity of landscape pattern that were not otherwise discernible using traditional morphometric parameters. The topographic characterization through the fractal patterns also presents an opportunity to analyze the innate nonlinearity in the geomorphic system. Fractal properties are useful to detect the heterogeneity in the degree of complexity in landscape pattern as well. Fractals have brought a significant change in the conventional ways of thinking about spatial forms, and complex natural landscapes are inherently amenable to these types of investigations.

Frequency Distribution

Ricardo A. Olea
Geology, Energy and Minerals Science Center,
U.S. Geological Survey, Reston, VA, USA

Definition

Given a numerical dataset, a frequency distribution is a summary displaying fluctuations of an attribute within the range of values. In contrast to an analytical probability distribution, a frequency distribution always deals with empirically observed values (Everitt and Skondall 2010). In general, the larger the number of values, the more useful the frequency distribution is relative to listing all values. Today multiple software packages allow easy display of a frequency

distribution. The dataset may be univariate or multivariate. For simplicity, this entry deals with univariate datasets.

Different Forms

In the broadest sense, a frequency distribution may be tabular or graphical. In either case, the most common practice is to classify the data into classes with the same interval length, also called bins. Table 1 and Fig. 1 provide an example comprising actual thickness measurements of a coal bed. The width of all classes in this illustrative example is 1 m. When the height of the class bars is proportional to the frequency, the graph is called a histogram. A less common practice is to display the same classes as a pie chart. Typically, the histogram is supplemented with a list of frequency distribution properties explained below.

The frequency table and the histogram in particular allow to quickly capture the main features in the style of the fluctuations. In the example, the values increase rapidly from close to zero to 3 m. Approximately 60% of the values are less than 3 m, which is close to only 20% of the range in thickness. An undesirable aspect of the histogram and the associated frequency table is that their appearance changes depending on the selection of the class interval. Although the details vary, the general trend may remain the same. For example, in the case of Fig. 1, by selecting five class intervals that are each 3 m wide, the first bar would be the tallest and the other bars would decrease in height systematically. In this example, details such as the initial increase in frequency or the local

Frequency Distribution, Table 1 Thickness of the Cherokee main bench at the Little Snake River coal field and Red Desert assessment area, Greater Green River Basin, Wyoming (Scott et al. 2019). The notation n^+ denotes a small number above n . The percentages are rounded to two decimal places.

Class interval Meters	Frequency Count	Frequency Percent
0–1	52	8.67
1 ⁺ –2	128	21.33
2 ⁺ –3	185	30.83
3 ⁺ –4	72	12.00
4 ⁺ –5	15	2.50
5 ⁺ –6	26	4.33
6 ⁺ –7	39	6.50
7 ⁺ –8	26	4.33
8 ⁺ –9	11	1.83
9 ⁺ –10	22	3.67
10 ⁺ –11	11	1.83
11 ⁺ –12	7	1.17
12 ⁺ –13	3	0.50
13 ⁺ –14	2	0.33
14 ⁺ –15	1	0.17
Total	600	100.00

Frequency Distribution,

Fig. 1 Thickness histogram of the main bench of the Cherokee coal bed, Wyoming (after Scott et al. 2019). All listed values are in the same units as the horizontal axis: meters

minimum between 4–5 m disappear. On the contrary, if there are too many bars as a result of taking too many classes, the histogram becomes noisy and it will be difficult to observe the relevant information, thus eliminating the main appeal of frequency distributions. There are no definitive rules concerning the optimal number of classes, but usually between 5 and 20 classes is an adequate number.

Statistics

The values listed in the histogram of Fig. 1 are numbers provided with the intention of further summarizing the data – statistics. The term sample size is just a different name for the number of data.

The rest of the statistics are primarily measures of location along the thickness axis. For example, the sum of all 600 thickness values is 2,150.968, which when divided by the total number of observations gives a value of 3.585 m. This value is called the mean, which can be interpreted as the central tendency of the dataset. Another central tendency value is the median, which is simply the value separating the half of lowest values from the half of highest values. In our illustrative example, this is the value between the 300th and 301st observations when the dataset is sorted, which is 2.438 m. One idea, but two clearly different values for the central tendency. Neither is a better indicator than the other, but the median is less sensitive to errors – more robust – especially for small sample sizes.

The idea of sorting the data and then dividing them into groups of equal sizes can be generalized from two to any other practical number of dividers (quantiles). Two of the most widely used number of classes are represented in the listing in Fig. 1: 4 and 100. Note that there is always one less divider than the number of groups. So, for four groups, there are three dividers. The divider separating the group of the smallest values from the group of the second smallest values is the lower quartile, which in this example is the value between the 150th and 151st values when sorted in increasing order; here it is 1.829 m. The divider between the two groups with the largest values is the upper quartile, which in this case is 4.725 m. The divider between the second and the third largest groups is still the median.

The dividers in a dataset sorted by increasing numbers and broken into 100 groups are called percentiles. The divider between the 5th lowest group and the next highest one is the 5th percentile. The 95th percentile is the divider between the 5th and the 6th highest groups. In terms of percentiles, the lower quartile and the upper quartile are the 25th and the 75th percentiles, respectively.

Next, we have the summary statistics of dispersion. The standard deviation, sd , is the only one of those statistics listed on Fig. 1. The calculation is more elaborate than those for the other statistics discussed so far:

$$sd = \sqrt{\frac{1}{n-1} \cdot \sum_{i=1}^n (z_i - m)^2}, \quad (1)$$

where n is the sample size, z_i is each one of the measurements, and m is the mean. The further apart are the measurements from the mean, the larger the value of the standard deviation is. The difference between the lower and the upper quartiles (interquartile range), and the difference between the 5th and the 95th percentile are two other measures of dispersion. In contrast to the standard deviation, these two intervals have an associated confidence interval: 50% of the values are between the lower and upper quartiles and 90% of them are between the 5th and the 95th percentiles. Hence, their information content is higher than that of the standard deviation.

Finally, the statistics in Fig. 1 can be used to describe the degree of symmetry of the frequency distribution with one value, which is calculated by subtracting the median from the mean. In this case, the result is 1.087 m. When the difference is positive, the frequency distribution tapers more slowly to the right; it is said to exhibit positive skewness. Positive skewness is typical in earth science datasets, particularly for geochemistry data. If the frequency distribution is symmetric, then the mean is equal to the median, but the converse is not necessarily true. Negative skewness implies a median larger than the mean.

Cautions and Warnings

Care must be taken to make sure that data have been collected properly so as to have representative samples (de Gruijter et al. 2006). In the case of the data in Fig. 1, more drilling was done where the coal bed was thicker, consequently the sampling is biased and the bias needs to be removed previous to any inference. Solutions in the presence of spatial correlation – which is the case of the example in Fig. 1 – involve weighting the data (Deutsch 1989) or selective discarding (Olea 2021).

In statistics, the collection of all possible measurements within a sampling domain is called a population sample, something close to impossible to attain in practice. A dataset such as the one in the example represents a minimal fraction of the population sample. However, ordinarily there is the interest and the need to use a partial sample to characterize the population sample. Several considerations are necessary for an adequate characterization.

Any parameter of the population frequency distribution is likely to be different from that of a partial sample; thus it is subject to uncertainty. The most convenient way to characterize the parameters of a population frequency distribution such as the median, the standard deviation, or any other parameter is to use the bootstrap method. The method provides the likely values for any of those parameters, thus allowing to see how low or how high the parameter actually could be.

If the partial sampling does not cover the entire area of interest, there is the possible complication that the frequency distribution is not going to be stationary: the frequency

distribution is different in different areas of the sampling domain. The only way to investigate or remedy this problem is with additional sampling.

Summary and Conclusions

The frequency distribution and related statistics are a straightforward way to have a dataset in a more understandable form than simply a listing of all measurements.

Frequency-Wavenumber Analysis

Frits Agterberg
Central Canada Division, Geomathematics Section,
Geological Survey of Canada, Ottawa, ON, Canada

Definition

Frequency-wavenumber analysis, also known as frequency-wavenumber spectral analysis, originated in atmospheric

physics where it is used to partition waves into standing and traveling varieties, the advantage of which is extraction of the different velocities of the traveling waves. This approach uses classical Fourier-series based methods commonly used in other branches of science. The common output of frequency-wavenumber analysis is a diagram in which frequency is plotted horizontally and a measure of spectral density along the vertical axis. Diagrams of this type are useful in geoscience, especially in multifractal modeling and for the study of data obtained from homogeneous geologic entities sampled equidistantly along straight lines; e.g., by drilling bore-holes.

Introduction

Cressie and Wikle (2011) have pointed out that statistics for spatiotemporal data constitute the next frontier in applications of mathematical statistics to geoscientific data. Much progress in this field has been made in atmospheric science (cf. Geoga et al. 2018; Simons and Wang 2011). In this chapter, the emphasis will be on frequency-wavenumber analysis as applied to equidistant solid Earth samples for which exact time measurements are not generally available. Time in solid Earth geoscience applications covers a broad spectrum ranging from nearly instantaneous events (e.g., earthquakes, volcanic eruptions, turbidity currents) to different types of long-term processes measured in millions of years with (or without) age determinations that are accompanied by relatively wide error bars. However, it is possible to apply methods of frequency-wave number analysis to sequences of chemical composition data and other measurements on rock samples. Spectral analysis of such data can provide valuable new insights. In addition to normal spectral analysis, attention in this entry will also be paid to applications of multifractal theory including frequency-wavenumber analysis without time measurements as originally derived in atmospheric physics (cf. Lovejoy and Schertzer 2013).

Sampling of Rocks: Pulacayo Zinc Deposit Example

Sampling of rocks at the surface of the Earth and performing measurements on them can be difficult because of limited exposure of bedrock but drilling often provides continuous sequences of measurements. At the microscopic scale, most rocks are heterogeneous consisting of different substances (e.g., different kinds of crystals) and volume of rock samples should not be too small. The purpose of the example given in this entry is to illustrate several of the problems encountered

when rock samples are collected for the purpose of chemical analysis. Normally, rocks are crushed before their chemical composition is determined on samples taken from the resulting powder. This aspect of rock sampling has been studied in detail by geochemists, chemists, and mineral engineers (see, e.g., Gy 2004). The primary example used in this entry concerns the spatial distribution of sphalerite crystals in relatively large “channel” samples from the Pulacayo mine in Bolivia.

De Wijs (1951) used a series of 118 zinc concentration values averaging 15.61% Zn from samples taken at a regular (2 m) interval along a horizontal drift on the 446-m mining level of the Pulacayo Mine in Bolivia. Level depth was measured downward from elevation of a tunnel along which the 2.7 km wide Tajo vein was discovered in 1883 and mined until 1956. This series shown graphically in Fig. 1 has been used extensively for later studies by many authors including Matheron (1962), Agterberg (1961, 1974, 2014), and Lovejoy and Schertzer (2007). The zinc values in Fig. 1 are for 1.3-m wide channel samples cut across this steeply dipping vein-type silver-zinc ore deposit.

Average sphalerite (zinc sulfide) content in the Tajo vein increased downward. Maximum possible zinc content is about 66% which is greater than the largest value of 39.3% zinc shown in Fig. 1. This is because the sampled material consisted not only of massive sulfide but also included mineralized wall rock, so that the largest possible value is considerably less than 66%. On the 446-m level, average thickness of massive vein filling averaged only 0.50 m but wall rocks on both sides of the vein contained disseminated sphalerite, partly occurring in subparallel stringers. The channel samples were cut over the standard width of 1.30 m that was the expected mining width. In size, they significantly exceed that of bore-hole samples obtained by drilling, thus reducing chemical measurement errors.

Figure 1 also shows a smoothed version of the 118 zinc values. It was based on the autocorrelation function shown in Fig. 2. The signal-plus-noise method used for the smoothing assumes that each zinc value is the sum of a “signal” component with continuous change along the series plus a random white-noise component. Together these two components produced an autocorrelation function of the type $\rho_h = c \cdot \exp(-ah)$ where h represents distance along the drift. Several other statistical methods such as simple moving averaging, ordinary kriging, or inverse distance weighting could be used to produce smoothed patterns similar to that shown in Fig. 1. Agterberg (1961) initially fitted a harmonic trend function to the zinc values using ordinary Fourier expansion that resulted in a curve which was smoother than those obtained by the other methods.

Frequency-Wavenumber Analysis, Fig. 1 Pulacayo Mine zinc concentration values for 118 2-m channel samples along horizontal drift samples (original data from De Wijs 1951). Sampling interval is 2 m. “Signal” retained after filtering out “Noise.” (Source: Agterberg 2012, Fig. 1)

Short-Distance Nugget Effect Modeling

In the preceding section, it was pointed out that there is uncertainty associated with the definition of “effective” channel sample length (L) in the Pulacayo Mine. Matheron (1963) set $L = 0.5$ because the Tajo vein has (horizontally measured) thickness of only 0.50 m on the 446-m level. This particular choice of L resulted in average zinc concentration estimates for lag distances greater than 2 m (up to 400 m). For shorter lag distances, however, it is useful to generalize Matheron’s concept by defining $A(L)$, which depends on the value of L .

In Agterberg (2012, Fig. 10) estimates of $A(L)$ are shown for effective channel sample lengths less than 0.5 m. For $L > 3$ cm, $A(L)$ increases slightly from about 0.01 to 0.0165 at $L = 0.5$ m; for $L < 0.03$ m, there is rapid decrease to $A(L) = 0$. Sums of squared deviations from lines of best fit for different values of L showed that the optimum solution $\alpha(L) = 0.021$ is obtained at $L = 13$ cm (Agterberg 2012). This implies that the negative exponential autocorrelation function previously used (see, e.g., Fig. 2) is too simple for short

distances ($h < 2$ m). The true pattern is closer to that shown in Fig. 3a, which differs from the earlier model in that strong autocorrelation is assumed to exist over very short distances. Rapid increase in autocorrelation near the origin is probably caused by localized clustering of ore crystals, although at the microscopic scale there remains rapid decorrelation related to crystal shape and measurement error. The model of Fig. 3 is an example of a nested semi-exponential autocorrelation function as previously used Serra (1966). It satisfies the equation:

$$\rho(h) = c_1 e^{-a_1 h} + c_2 e^{-a_2 h}$$

The coefficients in the first term are $c_1 = 0.5157$ and $a_1 = 0.1892$ as in Fig. 1. The second term represents the strong autocorrelation due to clustering over very short distances. Decorrelation at microscopic scale can be represented by a small white noise component (probably augmented with a random measurement error) with variance equal to

Frequency-Wavenumber Analysis, Fig. 2 Estimated autocorrelation coefficients for original data (in red) and logarithmically transformed Pulacayo zinc values (in blue), shown together with best-fitting negative exponential autocorrelation functions. The red and blue curves for

original and transformed data coincide approximately illustrating that logarithmic transformation of the original data does not significantly affect autocorrelation in this application. (Source: Agterberg 2012, Fig. 5)

$c_0 = 0.0208$ (Agterberg 2014, Section 11.3.1). The coefficient c_2 in the second term on the right side of the preceding equation satisfies $c_2 = 1 - c_0 - c_1 = 0.4635$. Choosing $a_2 = 2$ provides a good fit over the entire observed correlogram (Fig. 1). It affects extrapolation toward the origin with $h < 2$ m only. Figure 3b shows that the second term on the right side of the preceding nested design equation could not be detected in the correlogram for sampling intervals greater than 2 m.

The normalized power spectrum corresponding to the nested design of Fig. 3 is:

$$P(f) = \sum_{i=1}^2 \left[1 - c_i + \frac{c_i / \pi f_{ci}}{1 + (f/f_{ci})^2} \right]$$

where $f_{ci} = a_i / 2\pi$. A log-log plot of this spectrum is shown in Fig. 4 adopting the coefficients previously used for Fig. 3. The curve in Fig. 4 is approximately a straight line for lower

frequencies, but for high frequencies, there is a marked decrease of slope reflecting the nugget effect.

If n is even and the origin is chosen in the center of a series y_k ($k = 1, 2, \dots, n$), it can be written as:

$$y_k = a_0 + 2 \sum_{i=1}^{1/2n-1} \left[a_i \cos\left(\frac{2\pi i k}{n}\right) + b_i \sin\left(\frac{2\pi i k}{n}\right) \right] + a_{1/2n} \cos(\pi k)$$

Using amplitude and phase representation, this becomes:

$$y_k = R_0 + 2 \sum_{i=1}^{1/2n-1} \left[R_i \cos\left(\frac{2\pi i k}{n} + \varphi_i\right) + R_{1/2n} \cos(\pi k) \right]$$

where $R_i = \sqrt{a_i^2 + b_i^2}$ and $\varphi_i = \arctan\left(\frac{b_i}{a_i}\right)$. The periodogram is a plot of $P_i = R_i^2$ against I that is distributed as χ^2 with 2 degrees of freedom. The average of q consecutive

Frequency-Wavenumber Analysis, Fig. 3 Hypothetical autocorrelation function consisting of two negative exponentials to incorporate nugget effect over short lag distances h with $h < 2$ m. Autocorrelation function for nugget effect is superimposed on negative exponential curve for distances $h \geq 2$ m. (a) Vertical scale is linear; (b) vertical scale is logarithmic. (Source: Agterberg 2012, Fig. 12)

periodogram values provides an estimate of the power spectrum $E(P_i)$ that is distributed as χ^2 with approximately $2q$ degrees of freedom. The power spectrum of a continuous series is:

$$P_f = s^2(x) \int_{-\infty}^{\infty} r_h \cos(2\pi fh) dh$$

where r_h is the autocorrelation function. For example, if $r_h = c \cdot \exp.(-a \cdot |h|)$:

$$P(f) = (1 - c)s^2(x) + \frac{c \cdot s^2(x)/\pi f_c}{1 + (f/f_c)^2}.$$

Figure 5 shows the power spectrum $E(P_i)$ estimated by averaging pairs of consecutive values of the periodogram for the 118 zinc values together with a quadratic curve fitted by least squares. A best-fitting straight line for the same values results in $\beta = 0.72$ that can be shown to be significantly better

than the linear fit (for level of significance $\alpha = 0.01$). The slope of the curve at the origin in Fig. 5 gives $\beta = 1.18$ with gradually decrease to 0.49 at maximum log wave number on the right.

Universal Multifractals

Already in the 1980s, Schertzer and Lovejoy (1985) pointed out that the so-called binomial/ p model (also known as the model of de Wijs) can be regarded as a “micro-canonical” version of their α -model in which the strict condition of local preservation of mass is replaced by the more general condition of preservation of mass within larger neighborhoods (preservation of ensemble averages). Cascades of this type can result in lognormal distributions with Pareto tails as are encountered in the geosciences (cf. Agterberg 2021). In the three-parameter Lovejoy-Schertzer α -model, α (bold alpha) does not represent the singularity α but represents the so-called Lévy index that, together with the “codimension” C_1 and the “deviation from conservation” H , characterizes a universal multifractal field. Examples of applicability of universal multifractals to geological processes that took place in the Earth’s crust have been given by Lovejoy and Schertzer (2007).

The model originally developed by Schertzer and Lovejoy (1991) is based on the concept of a multifractal field ρ_λ with codimension $C_1(\gamma)$ where $\lambda = L/\epsilon$ is the scale ratio with L representing the largest scale that can be set equal to 1 without loss of generality (Cheng and Agterberg 1996). The field ρ_λ can be a flux or density in physics. In geochemical applications, it is the element concentration value of a chemical element. It is characterized by its probability distribution $P(\rho_\lambda \geq \lambda^\gamma \propto \lambda^{-C_1(\gamma)})$ with statistical moments $E(\rho_\lambda^q) \propto \lambda^{K(q)}$. The relations between $K(q)$, $C_1(\gamma)$, and the field order γ are:

$$K(q) = \max_{\gamma} \{q \cdot \gamma - C_1(\gamma)\}; C_1(\gamma) = \max_q \{q \cdot \gamma - K(q)\}$$

Cheng and Agterberg (1996) have made a systematic comparison of the binomial/ p model with the universal multifractal model of Schertzer and Lovejoy (1991). These authors have successfully applied their model to the 118 Pulacayo zinc values as will be discussed in the next.

The three-parameter α -model is a generalization of the conservative two-parameter $(0, C_1, \alpha)$ universal canonical multifractal (Schertzer and Lovejoy 1991, p. 59) model. So-called extremal Lévy variables play an important role in a two-parameter approach. In their large-value tail, these random variables have probability distributions of the Pareto form $P(X \geq x) \propto |x|^{-\alpha}$ ($\alpha < 2$). They can be used to generate multiplicative cascades starting from uniform random variables as follows. Suppose W is a uniform random variable within the interval $[0, 1]$ and $V = W^{-1/\alpha}$; so that the probability $P(V = v) = \alpha \cdot v^{-1-\alpha}$ if $v \geq 1$, and $P(V = v) = 0$ if $v < 1$ (cf. Wilson et al. 1991, APPENDIX B). Then, $\sum_{i=1}^n V_i$ representing the sum of n such random variables V_i ($i = 1,$

Frequency-Wavenumber Analysis, Fig. 4 Relative power spectrum for autocorrelation function of Fig. 3. Decrease in slope at higher frequency side is caused by the superimposed nugget effect. (Source: Agterberg 2012, Fig. 24)

2, ..., n) has a Lévy limit distribution with high-value tails. The Lévy index α defines another index α' by means of the relation $1/\alpha + 1/\alpha' = 1$. Suppose that μ and c are two constants and a new random variable is defined as $Y = c \cdot (\mu - V)$. Then, for large n : $Y = \frac{1}{n^{1/\alpha}} \sum_{i=1}^n c \cdot \left(\frac{\alpha}{\alpha-1} \cdot w_i^{-1/\alpha} \right)$ with Laplacian characteristic function $E(e^{Y \cdot q}) = \exp \{ \alpha \cdot \Gamma(-\alpha) \cdot (cq)^\alpha \}$. It follows, after some manipulation, that $c = \left(\frac{C_1}{\Gamma(2-\alpha)} \right)^{1/\alpha}$ resulting in the two-parameter universal form:

$$K(q) = \frac{C_1 \cdot \alpha'}{\alpha} (q^\alpha - q); \quad 0 \leq \alpha \leq 2; 0 < C_1 < E.$$

The Lévy index α characterizes the degree of multifractality and the codimension C_1 characterizes the sparseness of the mean field (Lovejoy and Schertzer 2010). In the three-parameter Lovejoy-Schertzer α -model, a third parameter H is added that characterizes the deviation from conservation. A space-time universal multifractal field for element concentration can be subject to change of its mean value in the course of time. Even in static 3D situations, incorporation of H into the model provides increased flexibility. Lovejoy and

Schertzer (2007) provide examples of geophysical data for which the universal multifractal approach is applicable.

Figure 6 taken from Lovejoy and Schertzer (2007) shows a realistic universal multifractal simulation for the Pulacayo orebody using the following three parameters: Lévy index $\alpha = 1.8$, codimension $C_1 = 0.03$, and deviation from conservation $H = 0.090$. This approach is explained in detail and illustrated by means of other applications in a large number of publications including Lovejoy and Schertzer (2013). The codimension C_1 , which characterizes sparseness of mean field, and deviation from conservation H can be derived as follows.

First a log-log plot of the so-called “first order structure function” is constructed. Successive moments are obtained for absolute values of differences between concentration values for points that are distance h apart by raising them to the powers q ($= 0.25, 0.5, \dots, 3$ for the 118 zinc values). The resulting pattern for $q = 2$ represents the variogram and the first point on the pattern for $q = 0$ is the de Wijs index of dispersion d . Straight lines are fitted to all patterns and a new diagram is constructed with the slopes of the lines (ξ_q) plotted against q . Slope and value of this new line near $q = 1$ yielded $H = 0.090$ and $C_1 = 0.02$ for the Pulacayo orebody because

Frequency-Wavenumber Analysis, Fig. 5 Periodogram of 118 zinc values with quadratic curve fitted by least squares (Logarithms base 10). The flattening of the curve toward higher frequencies is believed to be due to the nugget effect. (Source: Agterberg 2012, Fig. 25)

$H = \xi_l$ and $C_1 = H - \xi'_1$ where ξ'_1 is the first derivative of ξ_q with respect to q (Fig. 7).

Use of the so-called “double trace moment” method yielded estimates of the Lévy index equal to $\alpha = 1.76$ and $\alpha = 1.78$, and codimension $C_1 = 0.023, 0.022$, respectively (Fig. 8). In general, a relatively small value of C_1 with respect to H indicates that the multifractality is so weak that deviation from conservation (H) will be dominant except for quite large moments (Lovejoy and Schertzer 2007, p. 491). In the Pulacayo application, the estimated value of H is small and the two-parameter model of de Wijs would be approximately satisfied. As outlined before, the binomial/ p model produced inconsistencies between results for very small and very large moments. Universal multifractal modeling is more flexible and produces realistic zinc concentration variability. On the other hand, the estimate for the second-order moment obtained by the method of moments $\tau(2) = 0.979 \pm 0.038$ produced a realistic autocorrelation function including the nugget effect.

Frequency-wavenumber analysis is an important tool in universal multifractal modeling. Theoretically, the Lovejoy-Schertzer approach results in a spectrum consisting of a

straight line with slope $-\beta$. This parameter can either be estimated directly or indirectly using $\beta = 1 - K_2 + 2H$ where K_2 representing the “second characteristic function.” Lovejoy and Schertzer (2007) estimated $K_2 = 0.05$ by double trace moment analysis. With the previously mentioned estimate $H = 0.090$, this yielded $\beta \approx 1.12$ in good agreement with the experimental spectrum for the 118 zinc values previously shown in Fig. 5.

Summary and Conclusions

Frequency-wavenumber analysis is used in atmospheric physics to partition waves into standing and traveling varieties. The approach uses classical Fourier-series based methods. The common output of frequency-wavenumber analysis is a diagram in which frequency is plotted horizontally and a measure of spectral density along the vertical axis. This entry was concerned with applications of frequency-wavenumber analysis in solid Earth geoscience without use of the dimension of time for which sufficiently precise data are not available. Spectral analysis and multifractal modeling

Frequency-Wavenumber Analysis, Fig. 6

Result of experimental multifractal experiment by Lovejoy and Schertzer (2007, Fig. 3a). Blue: original Pulacayo zinc values, with x representing horizontal distance in units of 2 m. Pink: universal multifractal simulation results for Levy index $\alpha = 1.8$; codimension $C_1 = 0.03$ characterizing the “sparseness” of the mean field; and deviation from conservation $H = 0.090$. Both patterns were normalized to unity (mean = 15.6% Zn). (Source: Agterberg 2014, Fig. 12.33)

Frequency-Wavenumber Analysis, Fig. 7

Slopes $\xi(q)$ according to Lovejoy and Schertzer (2007, Fig. 26a). Slope and value near $q = 1$ yield $H = 0.090$, $C_1 = 0.018$, because $H = \xi(1)$ and $C_1 = H - \xi'(1)$; H represents deviation from conservation of pure multiplicative process for which $H = 0$. (Source: Agterberg 2014, Fig. 12.35)

Frequency-Wavenumber Analysis, Fig. 8

Lovejoy and Schertzer (2007, Fig. 27)'s double trace moment analysis of the Pulacayo zinc values with $q = 2$ (left), $q = 0.5$ (right). Slopes yield Levy index $\alpha = 1.76, 1.78$; and codimension $C_1 = 0.023, 0.022$, respectively. (Source: Agterberg 2014, Fig. 12.36)

were discussed and applied to the spatial distribution of zinc concentration values for equidistant elongated samples from the Pulacayo mine in Bolivia that previously have been studied by relatively many authors who took different points of view but reached similar results.

Definition

The Ful normal plot (FUNOP) is a graphical technique proposed by Tukey (1962) in his lead article *The Future of Data Analysis* useful in delineating outliers or other singularity in the data, in an automatic way. The FUNOP is often used as a starting point for a “vacuum cleaning” process, namely, a regression procedure for cleaning residuals (Anscombe and Tukey 1963).

The Method

Let $y_1, \dots, y_n$ be the n observed ordered values of a variable of interest. Let $\tilde{y}$ be their median (or let $\check{y}$, the 33% trimmed mean of the y_i). For $i \leq \frac{n}{3}$ or $i > \frac{2n}{3}$, let's define the Judd values as the deviation of the observations from the median divided by the standard normal deviate corresponding to the plotting-point percentage, thus

$$z_i = \frac{y_i - \tilde{y}}{q_i}, \quad (1)$$

or $z_i = \frac{y_i - \check{y}}{q_i}$, where q_i is the quantile of the standard normal distribution of order $i/(n+1)$, i.e., $q_i = \Phi^{-1}(i/(n+1))$, where Φ is the cumulative distribution function of a standard normal distribution or more conveniently $q_i = \Phi^{-1}((3i-1)/(3n+1))$ (Blom 1958, for numerical details). Let $\tilde{z}$ be the median of the Judds thus obtained (about two-thirds of the original sample size).

Note that each Judd value could be interpreted as the slope of the secant leading from the midpoint $(0, \tilde{y})$ to (q_i, y_i) and they are worthy of attention the more they deviate from the median point. By inspecting the Judds associated to the top and bottom thirds of the sorted population only, one can see if

Full Normal Plot, Fig. 1 Judds plotted against sorted original values (left) and sorted original values plotted against the theoretical distribution q_i (right). Tukey's example data

any of the observations seem to be unusually large or small, in particular Tukey recommends to give special attention to points whose slope is 1.5 or 2.0 times larger than the median (i.e., z_i for which $z_i \geq B_z$ with B equals to 1.5 or 2.0) (Koch and Link 1970–71). For the choice of B value, Tukey (1962) recognizes that it is going to be a matter of judgement and other values could be explored.

For data sets with small n , Tukey also recommend to give “special attention” to z_j with j more extreme than i for which z_i is selected following the previous criteria.

Application

Tukey's example (Tukey 1962) is used here to illustrate in practice the FUNOP technique. Figure 1 (left) shows Judds plotted against sorted original values. Grey dotted points refer to the middle-third of original values excluded from the analysis, and their median is indicated by the gray dotted line, green crosses represent non-suspicious data which belong to the upper and lower third of the sorted values according to Eq. (1), whereas red triangles mark special points which should deserve special attention. The dashed gray area in Fig. 1 (left) represents the region of points which exceeded 1.5 times the median z , indicated by the green horizontal dotted line. The first red triangle lies in this dashed gray area, whereas the second one is highlighted as it is more extreme than the ones already identified.

Figure 1 (right) shows sorted original values plotted against the theoretical distribution q_i . It is the standard Q-Q plot for normality, and ideally, the points should lie near the straight line which represents percentiles for the standard normal distribution. The red triangles, automatically marked by the FUNOP procedure as suspicious to be outliers, deviate

sharply from this line. FUNOP technique is successfully implemented in the R package vacuum Sielinski (2020).

The FUNOP to identify outliers is used by the FUNOR (full normal rejection) and FUNOM (full normal modification) procedures to treat them in the “vacuum cleaner” process (Tukey 1962). The usefulness of this procedure in an earth science context with geological data is discussed in Koch and Link (1970–71).

Summary

In this chapter the FUNOP, an automated procedures for detecting outliers, was presented as both general and accessible graphical technique in geosciences. The pattern of points in the plot suggest which observations should deserve “special attention.” It is noteworthy that the efforts of Tukey in detecting and dealing with outliers influenced succeeding Huber's work on robust estimation (Huber 1964; Hampel 1991).

However, we observe that, although presented in a fundamental article for the future of statistics, FUNOP is not very used in practice.

Fuzzy C-Means Clustering

Jaya Sreevalsan-Nair

Graphics-Visualization-Computing Lab, International
Institute of Information Technology Bangalore, Electronic
City, Bangalore, Karnataka, India

Definition

Clustering is a classical data mining method applied on a set of items to group like items, thus separating unlike items. Most clustering algorithms give a definite mapping of an item to a cluster, referred to as *hard clustering*. But in real world, an item can belong to multiple clusters with varying degrees of affinity to the cluster, given by a membership score. Consider that n items x_i , where $i = 0, 1, \dots, (n-1)$, in a dataset X are grouped in c clusters, given by C_j for $j = 0, 1, \dots, (c-1)$. Then, each item x_i of the finite set X has the flexibility of mapping to one or more clusters. Hence, a membership or affinity score is introduced here, u_{ij} , which is for item x_i with respect to C_j . This type of clustering is called *soft clustering*. Since it brings in an element of uncertainty by assigning probability values, i.e., u_{ij} , for mapping an item to a cluster, soft clustering is also called fuzzy clustering. An item must belong to one or more clusters, discarding the possibility of an item not belonging to any cluster, thus giving $u_{ij} > 0, \forall i \in [0, n-1]$ and $\forall j \in [0, c-1]$. This specific requirement along with the rule of sum of probabilities of all possibilities of the event, i.e., the item to a cluster mapping, also gives $\sum_{j=0}^{c-1} u_{ij} = 1.0, \forall i \in [0, n-1]$. Thus, the membership matrix $U = \{u_{ij}\}$ of size $n \times c$ provides the fuzzy c-partition (Bezdek 1981). Fuzzy c-means (FCM) clustering is an algorithm that provides the fuzzy c-partition.

Hard clustering can be derived from soft clustering by assigning rules, such as binarizing the membership score using a threshold, that will constraint the mapping of an

item to a single cluster. The binarization of the membership matrix leads to the outcome of compact well-separated clusters (Dunn 1973). If the constraints on membership scores are relaxed, such that $0 < u_{ij} \leq 1$ and $0 < \sum_{j=0}^{c-1} u_{ij} \leq c$, then the partition outcome is that of *possiblistic c-means*.

Overview

The application of the theory of fuzzy sets to cluster analysis by Ruspini in 1969 bore the earliest resemblance to the FCM algorithm (Bezdek 1981), the theory of fuzzy sets. The fuzzy set theory was developed in the 1960s, by several researchers independently as an alternative to the classical set theory. Particularly, Zadeh introduced an axiomatic structure, referred to as *fuzzy set*, in 1965, to combine the concepts of *imprecision* and *information* in mathematical models of grouping of entities. The aforementioned membership matrices with respect to soft and hard clustering correspond to the fuzzy and classical set theories, respectively. The original version of the FCM algorithm is attributed to the introduction of the fuzzy versions of the ISODATA clustering algorithm, which is a variant of K-means partitioning (Dunn 1973).

FCM is an iterative algorithm that uses optimization for finding the solution of the membership matrix U . Thus, FCM introduces a cost function $J_m(U, \mathbf{v})$ for the membership matrix U and the vector of cluster centers $\mathbf{v} = \{c_0, c_1, \dots, c_{(c-1)}\}$ in the m^{th} iteration. J_m has to be minimized during the algorithm, similar to K-means algorithm (see the article on “K-Means algorithm” for more details). Referred to as the fuzzy c-means functional, $J_m(U, \mathbf{v})$ is given by:

$$J_m(U, \mathbf{v}) = \sum_{i=0}^{(n-1)} \sum_{j=0}^{(c-1)} u_{ij}^m d_{ij}^2, \text{ where } d_{ij}^2 = \|x_i - c_j\|_2^2, \text{ and}$$

$$u_{ij} = \left(\sum_{k=0}^{(c-1)} \left(\frac{d_{ij}}{d_{ik}} \right)^{\frac{2}{m-1}} \right)^{-1}.$$

In later variants of the FCM algorithm, the distance d_{ij}^m can flexibly use diagonal norm or Mahalanobis distance, etc. in addition to the Euclidean or L_2 norm. The pairwise distance of items is computed between s -dimensional feature vector of the items. The FCM algorithm, as originally specified in (Bezdek 1973), is similar to the K-means algorithm. The FCM algorithm has two main steps of initialization and update. In the initialization step, c is fixed, such that $1 < c < n$, and the cluster centers in $\mathbf{v}$ is initialized. In the update step, U is computed using the current value of $\mathbf{v}$, followed by computation of $J_m(U, \mathbf{v})$, and then update $\mathbf{v}$. The computation

of the cluster centers is the weighted average of the membership values. Repeat the update step iteratively, and terminate when the matrix norm of the difference between the value of U in consecutive iterations is less than a threshold, ϵ_L , which is an infinitesimal value.

Since the introduction of FCM algorithm, it has been constantly improvised owing to its popularity as a probabilistic counterpart of the K-means clustering algorithm. One of the early improvisations was in using FCM with incomplete data, where some of the s -dimensional feature vector of the items has missing values (Hathaway and Bezdek 2001). If the amount of missing data is substantial, then one of the strategies is to compute partial distance, i.e., compute distances between only part of the vector which is complete. A second strategy for modifying FCM is in determining the optimal values for the missing values, such that the FCM functional $J_m(U, \nu)$, is minimized. A third strategy is in identifying the nearest neighbor using partial strategy, and use the values in the neighbor to fill out the missing values in the current item. Overall, the optimal completion strategy has given the best results.

FCM is sensitive to the distance metric used in the computation of U that also affect the computations of ν and J_m (Wang et al. 2004). This distance measure can be improved by using the weighted Euclidean distances where the weights are learnt using a gradient descent method. This method introduces a measure of fuzziness in the similarity between two items, which are represented using s -dimensional feature vector. If the similarity value is 0 or 1, then it is discernable, but if the similarity value is close to 0.5, then the fuzziness is increased. The fuzziness of an iteration of the FCM is the aggregate sum of the fuzziness across all elements. The fuzziness is further encapsulated in an evaluation function, which is minimized. The argument of the minimum value of the evaluation functions provides the weights for the feature-weight learning process. While the clustering outcomes have improved, the tradeoff with the original FCM algorithm is that the time complexity has increased to $O(cn^2)$.

For evaluating the clustering outcomes, cluster validity measures are required for fuzzy clusters similar to the clear well-separated clusters from hard clustering (Pakhira et al. 2004). The latter is also referred to as crisp clusters. While the Dunn's index and Davies-Bouldin index are exclusively for crisp clusters, the Xie-Beni (XB) index has been used for fuzzy clusters. The XB index is given as a ratio of the intra-cluster sum of squared distances to the minimum inter-cluster, and the ratio is normalized by the number of items. Various new validity indices for fuzzy clusters have been proposed in the 2000s and later, which improve upon the XB index. For instance, a PBM index has been proposed which does better for both elliptical and circular shaped clusters, unlike the XB index that fails for the elliptical shapes.

Applications with a Focus on Image Processing

FCM can find several uses in geosciences including clustering a certain set of objects as well as clustering within a data item with spatial context, e.g., images. Here, the applications of FCM in image processing problems are discussed. FCM itself can be improved to work with spatial datasets, such as images, where spatial contiguity must be preserved in the clustering outcome (Chuang et al. 2006). This application of clustering is on pixels, thus leading to image segmentation. For spatial FCM, the membership score is computed using weights which use the results of convolution of specific kernels in the $k \times k$ pixel neighborhood of each pixel in the image. Thus, introducing the spatial weights in the computation of the membership matrix facilitates preserving spatial contiguity in the FCM clustering outcomes. FCM clustering is especially useful in segmentation of multispectral images (Tran et al. 2005). Even with high resolution scanners, the pixels in multispectral images tend to contain the spectral response of several components. Thus, overlapping clusters naturally exist in such images. Thus, FCM is a better fit for mapping pixels to components in such an application instead of the K-means algorithm.

A similar segmentation with the use of FCM has been used for change detection in landslide mapping (Lei et al. 2018). In this application, firstly, a fast implementation of FCM provides the segmentation to candidate and non-landslide regions in the very high-resolution (VHR) remote sensing images. Then, the segmentation result is further refined using analysis of the difference image. This method has been found to be more superior than level-set and Markov chain-based methods in terms of increased accuracy, reduced parameter tuning, and faster execution. FCM can also be used in conjunction with other data science methods, such as Markov random field (MRF) for improved results of segmentation.

Future Scope

Given the popularity of the FCM clustering algorithm, there has been a constant effort in improving the accuracy and the efficiency of its implementation since the 1980s. One of the earliest attempts at efficient implementation involves the use of approximate values, which are accessed efficiently using a lookup table (Cannon et al. 1986). The lookup table helps in efficient computation of Euclidean distances. This has considerably reduced the execution time on the CPU (central processing unit). In the state of the art, the implementation has been further improved through parallel implementation on multiple processing units, such as the CPUs and GPUs.

The newer challenges in the implementation of FCM are pertaining to the large size of the datasets (Havens et al. 2012). Various strategies prevalent for handling large-scale datasets can be applied in the case of FCM clustering, such as sampling, incremental techniques, and kernelized variants of FCM. The kernel algorithms have been found to have higher time complexity in comparison to the vector-based counterparts. In general, all of these algorithms are motivated to reduce space complexity, followed by reduction in time complexity.

In this article, several aspects of FCM clustering and its geoscientific applications have been discussed. FCM clustering has been proven to be an effective data processing technique for image segmentation, typhoon tracking, change detection in SAR images, and similar other applications.

Definition

A Fuzzy Inference System (FIS) is a system containing a set of *if-then* rules expressed in natural language to simulate inductive reasoning of an expert (Porwal et al. 2015). It is a knowledge-driven inference engine built upon the theory of fuzzy sets. A *fuzzy set* is the extension of a classical set and does not have clearly defined limits. The degree of membership to fuzzy sets grades from 0 to 1 (unlike classical sets, where it is either 0 or 1) (Zadeh 1973). A fuzzy set, hence, allows for a simplified representation of real-world phenomena including geological processes (see “Fuzzy Set Theory in Geosciences”). When more than one fuzzy set are identified in a dataset and combined using logical operators, it forms a fuzzy logic overlay. Numerous fuzzy logic overlays expressed as *if-then* rules and integrated in an inference engine encompass a FIS. A FIS has the capabilities to capture the imprecision and vagueness of natural phenomena within a single system. Genesis of mineral deposits is a result of interplay of stochastic geological processes. This entry describes the application of FISs for modeling these processes and thereby guiding mineral exploration activities.

FIS for Mineral Exploration

The concept of FIS was formulated in the early works on fuzzy logic by Zadeh (1973). Consequent development of FISs for industrial applications is described in Mamdani and Assilian (1975). The FISs are also known as fuzzy-rule-based systems, fuzzy models, fuzzy associative memories (FAM), or fuzzy controllers when used as controllers (Jang 1993).

In the field of mineral exploration, the initial studies involved the use of fuzzy logic overlays (see “Fuzzy Set Theory in Geosciences”). However, the earliest application of FIS to mineral exploration was by Porwal et al. (2004) for mineral prospectivity modeling. Quantifying the possibility

of finding a mineral deposit in a geographic region by mathematical integration of geological variables (representing mineralization processes) is known as mineral prospectivity modeling. Mineral prospectivity modeling can be implemented using different methods ranging from data-driven regression to knowledge-driven expert systems. FISs are intuitive and advanced knowledge-driven systems that can be used for guiding mineral exploration activities at varying scales of prospectivity modeling (Porwal et al. 2015).

Architecture of a FIS

The generic architecture of a rule-based FIS is shown in Fig. 1. The components of a FIS are:

1. Fuzzy set: Let X represent the universal set of values x of a geological variable, such as elemental concentration or distance to a geological feature. A Fuzzy set $\tilde{A}$ in X is a mathematical representation of the expert knowledge of the range of values of X , which is otherwise expressed in natural language. Fuzzy sets are assigned linguistic labels such as “proximal” (e.g., close to a geological feature), “high” (e.g., anomalously large elemental concentrations), and so on. Mathematically, a fuzzy set is a set of ordered pairs, such that:

$$\tilde{A} = \{(x, \mu_{\tilde{A}}(x)) | x \in X\} \quad (1)$$

where $\mu_{\tilde{A}} \in [0,1]$ is the degree of membership of x in $\tilde{A}$.

2. Fuzzy membership function (FMF): An FMF is a mathematical function, such as linear, Gaussian, or sigmoid, that transforms the numeric values of an input variable to the degree of membership in the corresponding fuzzy set. Selection of FMF is based on its ability to represent the influence of a geological feature on modeled geological phenomenon. For instance, Fig. 2 shows a fuzzy set $\tilde{A}$, with linguistic label *Proximal*, defined on set X : *distance to a geological feature* having a degree of membership, $\mu_{\tilde{A}}$ computed using a Gaussian FMF.
3. Fuzzy operators: Fuzzy operators are logical operators that integrate the fuzzy sets in a FIS. These are the building blocks of the *if-then* rules. The three basic fuzzy operators are OR (disjunction), AND (conjunction), and NOT (complement) that perform the union, intersection, and complement of the fuzzy sets, respectively (Fig. 3). Binary t-norm and t-conorm operators can also be used. These enable the generalization of the union and intersection operators, respectively.

4. Fuzzy rules: Fuzzy *if-then* rules are conditional statements formulated to impart logical reasoning to the inference engine. They contain fuzzy sets connected by the operators. A single fuzzy *if-then* rule is in the form of:

$$\text{IF } x \text{ is } A \text{ AND } y \text{ is } B, \text{ THEN } z \text{ is } C \quad (2)$$

where A and B are fuzzy sets in the input variables x and y , respectively, and C is a fuzzy set in the output variable z . The *if* part of the statement (a.k.a. antecedent) defines the condition or the premise of the input variables and the *then* part (a.k.a. consequent) models the output conclusion or the consequence for the given input premises.

5. Defuzzifier: The defuzzifier in a FIS converts the consequent values aggregated across all rules to a crisp numeric output value. The common defuzzification methods are centroid of area, bisector of area, mean of maximum, smallest of maximum, and largest of maximum.

Types of FISs

There are two types of FISs: (1) a Mamdani-type FIS (Mamdani and Assilian 1975), and (2) a Takagi-Sugeno-type (T-S) FIS (Takagi and Sugeno 1985). In a Mamdani-type FIS (Figs. 1 and 4) the output variable in the consequent part comprises fuzzy sets defined by different output membership functions (Eq. 2). For instance, in Fig. 4 the output variable *chemical traps potential* comprises three fuzzy sets *High*, *Moderate*, and *Low*. The degree of membership to these fuzzy sets is defined by Gaussian FMFs of varying parameters. In contrast, a T-S FIS is of the format:

$$\text{IF } x \text{ is } A \text{ AND } y \text{ is } B, \text{ THEN } Z = f(x, y), \quad (3)$$

where $f(x, y)$ is a zero- or a first-degree polynomial function of the input variables.

The Mamdani- and T-S-type FISs are knowledge-driven. Jang (1993) demonstrated an adaptive neuro fuzzy inference system (ANFIS), which is a hybrid type of T-S FIS. In an ANFIS the hybrid learning procedure combines the least square estimators and the gradient descent algorithm for parameterization of the FIS.

Example of a FIS Designed for Gold Mineralization

Figure 4 shows an example of a hypothetical Mamdani-type FIS (Mamdani and Assilian 1975) designed for modeling

Fuzzy Inference Systems for Mineral Exploration,

Fig. 1 Generic architecture of a rule-based FIS with one if-then rule

Fuzzy Inference Systems for Mineral Exploration, Fig. 2 Continuous fuzzy membership function for a fuzzy set 'Proximal' in a universal set "Distance to a Geological Feature"

gold mineralization based on the potential of chemical traps. It contains three input evidence layers representing X: distance to Fe-rich rocks, Y: relative conductivity of rocks, and Z: density of lithological contacts weighted by reactivity

contrasts across the contacts. These input variables are combined in logical statements using the following fuzzy *if-then* rules:

Fuzzy Inference Systems for Mineral Exploration, Fig. 3 Fuzzy-overlay operators – OR, AND, and NOT

- (i) IF Fe-rich rocks are *Proximal* AND Relative conductivity is *High* AND Density of lithological contacts is *High* THEN Chemical Traps Potential is *High*.
- (ii) IF Fe-rich rocks are *In the vicinity* AND Relative conductivity is *Moderate* and Density of lithological contacts is *Moderate* THEN Chemical Traps Potential is *Moderate*.
- (iii) IF Fe-rich rocks are *Distant* AND Relative conductivity is *Low* and Density of lithological contacts is *Low* THEN Chemical Traps Potential is *Low*.

In the above rules, the linguistic values – *proximal*, *in the vicinity*, *distant*, *high*, *moderate*, and *low*, are the fuzzy sets combined using the conjunction operator, AND, for fuzzy overlay in the inference engine. For input values $X = 0.35$, $Y = 0.6$ and $Z = 0.5$, rules i and ii are activated and the chemical traps potential is mapped to the output fuzzy sets *High* and *Moderate*, respectively. Defuzzification using the centroid method translates the fuzzy linguistic values to a crisp numerical value of 0.505 for the *chemical traps potential*. Depending upon the unique feature vectors present in a given dataset, different rule(s) of the FIS can get activated. The corresponding output potential is defuzzified from the

Fuzzy Inference Systems for Mineral Exploration, Fig. 4 Three-if-then rule-based Mamdani-type FIS modeling potential of favorable chemical traps for gold mineralization

aggregate of the *consequents* of all the activated rules using a defuzzifier.

Selected Case Studies

In contrast to purely data-driven techniques, the possibility of incorporating knowledge based on geological expertise has motivated the choice of FIS for efficient modeling of mineralization processes, as demonstrated in recent studies. Porwal et al. (2015) developed and implemented a Mamdani-type FIS with 34 *if-then* rules for prospectivity modeling of surficial uranium deposits in the Yeelirrie area in Western Australia (WA). This study identified several palaeochannels in their study area as highly prospective for mineralization. The palaeochannels in the Deserts and Xeric Shrublands biome in WA are geologically and climatically important areas for formation of surficial uranium deposits. Building from the proto-FIS presented by Porwal et al. (2015), Chudasama et al. (2018) implemented a multistage FIS-based regional scale prospectivity modeling of surficial uranium mineralization in the palaeochannels of WA. The sources and traps components of the surficial uranium mineral system were modeled individually using Mamdani-type FISs. The study identified new greenfields areas for surficial uranium deposits in the less-explored Paterson orogen and Musgraves block.

Chudasama et al. (2016) presented a two-stage Mamdani-type FIS-based prospectivity modeling of orogenic gold mineralization in the Palaeoproterozoic Kumasi Basin in Ghana. Their results identified high prospectivity zones along the structural trends of known mineral deposits capturing the strong spatial association between the known deposits and the metallogenic trends in the area. Of the 32 in situ gold deposits, the model mapped 78% of these within areas of high prospectivity values. New areas identified from the results were taken up for ground exploration by the lease holding company.

Porwal et al. (2004) applied an ANFIS to model base metal mineralization potential in the Aravalli metallogenic province in western India. The Aravalli province contains significant reserves of base metal sulfide deposits, particularly lead and zinc, including the world class Rampura-Agucha deposit. This was a first study where a T-S ANFIS trained using a four-layered feed-forward adaptive neural network was applied to mineral prospectivity modeling. The results captured 96% of the known base metal deposits within 9.75% of the study area and greatly reduced the search areas for guiding further ground exploration activities.

The collective results of the above studies demonstrate that FIS models can be effectively applied (1) for modeling mineralization processes at regional-scales, (2) to aid identification of prospect-scale targets, and (3) to locate drilling areas for expansion of known resources.

Summary and Conclusions

Geological processes leading to formation of mineral deposits are complex and mathematically nondeterministic. Quantification of these processes by a single or hierarchical fuzzy logic overlay leads to an oversimplified representation of the intricate mineral systems. Hence when applied to mineral prospectivity modeling, FISs are powerful at simulating mineralization-related complex geological processes. A FIS is enhanced by the deductive reasoning of the geoscientist for modeling these processes. Being knowledge-driven they are not restricted to learning deposit-specific geological features, but instead are capable of comprehensively modeling mineralization processes. Additionally, in data-rich areas, neuro-fuzzy framework can impart learning capabilities to a T-S FIS for efficient modeling of the targeted mineral system. FISs are hence intuitive and capable of incorporating human cognition and the complex geoscientific reasoning required for mineral exploration activities.

Definition

Fuzzy set was introduced by Zadeh (1965- see the entry “Zadeh, Lotfi A.”) as a set whose membership ranges from 0 to 1. The label of a fuzzy set is a linguistic value. For numerical data, the conversion of each data value to fuzzy membership is through a fuzzy membership function. Formally, let X be a set whose elements are represented generically as x . A fuzzy set $\tilde{A}$ in X is a set of ordered pairs:

$$\tilde{A} = \{(x, \mu_{\tilde{A}}(x)) | x \in X\}.$$

where $\mu_{\tilde{A}}$ is the membership function (degree of compatibility or degree of truth) of x in $\tilde{A}$. The fuzzy set $\tilde{A}$ becomes a classical set if its membership value is restricted to either 0 or 1.

Introduction of Fuzzy Set Theory

The membership of a traditional binary set is confined to 1 or 0, implying that an object can either be a member of the set or not a member of the set. The binary set theory therefore disallows partial memberships, which is a major limitation particularly when dealing with poorly constrained and ill-defined phenomenon. The theory of fuzzy sets extends the membership to a value between 0 and 1, thus allowing partial membership of objects in a set. The fuzzy membership value represents the degree of truth that an object is a membership of a given set. Consider, for example, a set defined by high copper anomalies. If this set is considered a binary set, then a given sample can be a member of this set or not a member of

this set. However, it is often difficult to decide the threshold at which a given sample value becomes a member. A fuzzy set requires no such hard thresholding of values, and all sample values are considered members. The membership value defines the degree of truth that a given sample value is indeed a high anomaly.

Geospatial phenomena and processes are often vaguely defined and inherently fuzzy. The variables of geospatial processes are poorly constrained and often described in terms of linguistic values. Therefore, the fuzzy set theory has wide-ranging applications in modeling and predicting geospatial events. The most important process for this sake is assigning the proper membership values to the available data layers considering their importance in the final inference for a more efficient interpretation based on the combined data layers and evidential maps. Such maps are generated using either qualitative analysis (called “knowledge-driven approach”) or quantitative analysis (called “data-driven approach”) (Carranza 2009). In the former one, the fuzzy membership values are assigned by the expert considering the relevant knowledge and experience, but in the latter one, the fuzzy membership values are assigned based on the available exploration data. Such evidential maps are combined considering all the assigned membership values to come up with a single representative map. Then the defuzzification process is applied to the map to define the targets (e.g., mineral exploration targets). Fuzzy sets are more suitable for describing imprecise parameters.

To combine fuzzy sets, a set of operators have been proposed by Zadeh (1965) and Zimmermann (1991). For example, fuzzy AND is a minimum operator, fuzzy OR is a maximum operator, fuzzy algebraic sum and fuzzy algebraic product are types of product operators, the NOT is an exclusion operator, and fuzzy gamma (γ) combines algebraic sum and algebraic product operators (Table 1). These rules and operators allocate a complete fuzzy set to the output over the insinuation process by combination processes for decision-making.

The fuzzy AND and PRODUCT operators should be used where both datasets are necessary for ascertaining the truth of the proposition, while the OR and SUM operators should be used if one dataset is sufficient for ascertaining the truth of the proposition. Obviously, the output of the fuzzy AND operator carries higher confidence.

The fuzzy gamma operator balances the increase and decrease tendencies of the fuzzy algebraic summation and product, respectively, as below:

$$F_{\text{Combination}} = (\text{Fuzzy Algebraic Sum}^{\gamma}) \times (\text{Fuzzy Algebraic Product}^{1-\gamma})$$

For $\gamma = 0$, the output is the same as that of the fuzzy product. As the value of γ increases, the output tends towards

Fuzzy Set Theory in Geosciences, Table 1 The descriptions and equations of the fuzzy AND, fuzzy OR, fuzzy algebraic product, fuzzy algebraic sum, and fuzzy gamma operators (Carranza and Hale 2001; Nykänen et al. 2008)

Operator	Equation*	Description
Fuzzy AND	$\mu_{\text{combination}} = \text{Min}(\mu_A, \mu_B, \mu_C, \dots)$	Minimum operator, equivalent to Boolean AND (logical intersection)
Fuzzy OR	$\mu_{\text{combination}} = \text{Max}(\mu_A, \mu_B, \mu_C, \dots)$	Maximum operator, equivalent to Boolean OR (logical union)
Fuzzy algebraic product	$\mu_{\text{combination}} = \prod_{i=1}^n \mu_i$	The output results always smaller or equal to the smallest contributing fuzzy membership value
Fuzzy algebraic sum	$\mu_{\text{combination}} = 1 - \prod_{i=1}^n (1 - \mu_i)$	Complementary to the fuzzy algebraic product. The output results are always larger or equal to the largest contributing fuzzy membership value
Fuzzy gamma (γ)	$\mu_{\text{combination}} = \left(\prod_{i=1}^n \mu_i \right)^{1-\gamma} - \left(1 - \prod_{i=1}^n (1 - \mu_i) \right)^{\gamma}$	Fuzzy gamma operator is an amalgamation of the fuzzy algebraic product and the fuzzy algebraic sum; it is a parameter chosen in the range of [0,1] (Zimmermann and Zysno 1980). Cautious choice of gamma produces output values that confirm a flexible compromise between the increasive tendencies of the fuzzy algebraic sum and the decreaseive effects of the fuzzy algebraic product.

* μ_n defines a membership value for map n at a particular location ($n = A, B, \dots$). Also, μ_i is the fuzzy membership values for the i th ($i = 1, 2, \dots, n$) map to be combined

Fuzzy Set Theory in Geosciences, Fig. 1 Fuzzy logic modeling steps. (Modified from Porwal et al. 2003)

the fuzzy SUM, and for $\gamma = 1$, the output is the equal to that of the fuzzy SUM.

Stages of Fuzzy Logic Modeling

Fuzzy Logic modeling has three main steps in general that should be applied to the evidential data (Porwal et al. 2003) (Fig. 1): (I) fuzzification (encoding); (II) logical integration using inference engine and fuzzy set operations; and (III) defuzzification (decoding).

The input datasets could be categorical or numerical. All the available datasets are individually imported, then a fuzzifier converts them into fuzzy values of membership, using a membership function $\mu_A(x)$, in a continuous range between 0 (also called “false,” “non-membership,” and “incomplete”) and 1 (also called “true,” “full membership,” and “complete”), respectively. In general, $\mu_A(x)$ is defined based on a priori *knowledge* of the geological system or using training data (Porwal et al. 2003). In general, the fuzzy membership values represent the importance of an input geospatial variable in the geospatial process being modelled. The individual fuzzy sets are then combined

using a number of parallel and/or serial networks that sequentially combine fuzzy sets through fuzzy operators. The design of the inference engine should simulate the geospatial process being modelled (Porwal et al. 2003). The output of the inference engine is a synthesized fuzzy set of data, which is transmitted then to the defuzzifier. Here, a back-transformation process is taken place by a defuzzification mathematical function or any specific threshold fuzzy grade already defined (see Hellendoorn and Thomas 1993). In other words, defuzzification is the process of altering the combination result into a crisp output, e.g., centroid, bisector, middle of maximum (the average of the maximum value of the output set), largest of maximum, and smallest of maximum.

Further Definition Using Various Case Studies

Zimmerman (2001) is a good source to understand fuzzy set theory and its various applications. In geosciences, still Demicco and Klir (2004) with an interesting foreword by Zadeh is one of the best sourcebooks for geoscientists to gain a proper overview regarding the application of fuzzy

logic modeling in different fields of geosciences such as geology, stratigraphic modeling, hydrology and water resources, earthquake research, and sea level estimation. In the field of mineral potential mapping (MPM) using geochemical data (see the entries “Exploration Geochemistry”

and “Mineral Prospectivity Analysis”), Carranza (2009) as the other proper sourcebook has provided interesting demonstrations and details. In geostatistics and modeling spatial uncertainty Chilès and Delfiner (2012) and Caers (2011)

Fuzzy Set Theory in Geosciences, Fig. 2 Target areas detected by the fuzzy logic method (from Sadeghi and Khalajmasoumi 2015). Data layers on the top from left to right: hot springs, volcanoes, volcanic and intrusive rocks, and faults and fractures

provide clear descriptions. In the following section, several case studies are briefly reviewed.

Geothermal Resource Exploration

Due to the climate change and global warming critical consequences, new sources of renewable and sustainable energy and their applications have been taken into serious consideration. Among such sources, the one highly related to geosciences is geothermal (see the entry “Geothermal Energy”). For example, Iceland, Japan, and New Zealand are among the most advanced countries around the world

that have made a great progress in using geothermal energy for a variety of applications such as electricity generation.

From geological point of view, geothermal resources could be discovered in a variety of geological systems such as volcanic rocks, limestones, and shales (Kiavarz Moghaddam et al. 2014). Acidic volcanic and intrusive rocks are considered as the main practical sources of geothermal energy for the industry (Manzella 2007; Huenges 2010).

Geothermal energy is found in either liquid-dominated (over 200°C) or vapor-dominated (with 240°C to 300°C) forms (Sadeghi and Khalajmasoumi 2015), mostly near young volcanoes around the Pacific Ocean, rifts and hot spots, faults, and geothermal alterations (Dickson and Fanelli 2004). Discharge systems such as mud volcanoes and geysers

Fuzzy Set Theory in Geosciences, Fig. 3 (a) The methodology outline applied in this study; (b) mineral potential map of the KKTZ region in Central Iran generated from Landsat-8, Sentinel-2, ASTER, and WV-3 data. (Modified from Sekandari et al. 2020)

Fuzzy Set Theory in Geosciences, Table 2 Fuzzification parameters for the input layers

Data origin	Input layer	Detection	Membership type	Fuzzy operator
Landsat-8 dataset	PCA4	OH-minerals and carbonates	Linear	AND
	PCA5	Iron oxide		
Sentinel-2 dataset	PCA4	OH-minerals and carbonates	Linear	Gamma ($\gamma = 0.6$)
	PCA5	Iron oxide		
ASTER dataset	PCA4	Iron oxide/hydroxides minerals	Linear	AND
	PCA5	OH/S-O/CO ₃ -bearing minerals		
	PCA8	Dolomite		
World-View3 dataset	PCA3	Iron-stained alteration	Linear	AND
	PCA4	Dolomite/Fe ²⁺ oxides		
	PCA6	Fe ³⁺ oxides		

are the other superficial indicators of geothermal systems. They mostly come with hydrothermal alterations.

In geosciences there are two main types of uncertainties including (i) stochastic uncertainty and (ii) systematic uncertainty (Porwal et al. 2003; Sadeghi 2020 – see the entry “Uncertainty Quantification”). Simply, fuzziness is the reason of such vagueness and uncertainties. Geothermal system exploration always comes with a high relevant uncertainties and financial risk. Therefore, making the best decision considering all the available data layers could be highly helpful in reducing such uncertainties and the consequent risks.

As a case study, we refer to Sadeghi and Khalajmasoumi (2015), who focused their study on Eastern Azarbayegan Province in NW Iran. In their study, the main data layers taken into account were (1) volcanoes, (2) faults and fractures, (3) hot springs, and (4) volcanic and intrusive rocks. In this case study, based on the expert’s knowledge, SUM was applied to the layers of hot springs and volcanoes, and OR was applied to the layers of faults and volcanic-intrusive rocks. Also, 95% was assigned to γ . In the final processed map (Fig. 2), it turned out that the central part of the study area, including the blue and purple representative areas, is the best area to focus the follow-up exploration and drilling projects on.

Exploration Geology Using Remote Sensing Data

Remote sensing data are efficaciously used for alteration and lithological and structural mapping (El-Wahed et al. 2021;

Pour et al. 2021). Fuzzy logic modeling (FLM) is effectively implemented to remote sensing data to integrate thematic layers extracted from the data for MPM in a variety of metallogenic provinces around the world (cf. Porwal et al. 2003; Tangestani and Moore 2003; Ranjbar and Honarmand 2004; Rahimzadegan et al. 2015; Sekandari et al. 2020; Wambo et al. 2020; Shirmard et al. 2020; Moradpour et al. 2021). For example, Sekandari et al. (2020) used FLM to integrate the thematic layers derived from Landsat-8, Sentinel-2, Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), and WorldView-3(WV-3) satellite remote sensing data for generating mineral potential maps of Carbonate-Hosted Pb-Zn Deposits in the Kashmar-Kerman Tectonic Zone (KKTZ), Central Iran. Band ratios and principal component analysis (PCA) image processing techniques were applied for mapping alteration minerals and lithological units. Then, the thematic layers of the alteration zones were integrated using FLM to produce mineral potential maps. An outline of the methodological flowchart applied in this study is demonstrated in Fig. 3a. In this study, the multiclass evidential layers were reclassified to 10 classes of equal intervals and then were fuzzified using the linear membership function. The fuzzy AND operator was applied to map the prospective areas by Landsat-8 and Sentinel-2 and WV-3 alteration thematic layers. The fuzzy gamma operator was implemented to ASTER alteration thematic layers. Table 2 shows fuzzification parameters for the input layers. Several high potential zones were identified in KKTZ. Figure 3b shows the KKTZ mineral potential map produced using Landsat-8, Sentinel-2, ASTER, and WV-3 data.

Fuzzy Set Theory in Geosciences, Fig. 5 (a) Regional scale potential map of Ngoura-Colomines goldfield, Eastern Cameroon, generated based on Landsat-8 data; (b) mineral potential map of the southwestern zone of Ngoura-Colomines goldfield generated using ASTER data; and (c) mineral potential map of the southeastern zone of Ngoura-Colomines goldfield generated based on ASTER data. (Modified from Wambo et al. 2020)

Fuzzy Set Theory in Geosciences, Table 3 Fuzzification parameters for the input layers

Data origin		Data	Selected input layer	Membership type	Fuzzy operator		
	Field laboratory	Geochemical data	Cu, Zn, and Au	Linear	AND		Gamma ($\gamma = 0.9$)
	ASTER dataset	Structure map	Intersection of NE–SW and NW–SE lineaments		OR		
			high lines density zone				
		MF fraction images of n-D class #1 and n-D class #5	Al-OH and Fe, Mg-O-H minerals and jarosite		OR	AND	
		IC4 Image	Sericitically argillically altered minerals in association with jarosite and chlorite/epidote		OR		
	Geological map	Weighted lithology	Lithologies associated with gold mineralization (weighted 3– 5)	–			

Additionally, Shirmard et al. (2020) utilized the FLM to integrate the thematic layers derived from PCA, independent component analysis (ICA) and minimum noise fraction (MNF) techniques applied to ASTER data for generating evidential layers for MPM in the Toroud-Chahshirin range, Central Iran. Numerous prospective zones were discovered using the fused hydrothermal alteration map. The flowchart of methodology used in this study is shown in Fig. 4a. Figure 4b shows the potential map of Toroud-Chahshirin region.

The potential mineral maps produced from thematic layers of alteration minerals using FLM can be fused with other geological maps such as structural and lithological maps and geochemical and geophysical anomaly maps to generate metallogenic provinces' mineral potential models. For example, Wambo et al. (2020) implemented the FLM to alteration thematic layers derived from Landsat-8 and ASTER remote sensing data to identify high potential zones of gold mineralization in the Ngoura-Colomines goldfield, Eastern Cameroon. The resultant mineral potential maps were fused with structural maps of the study area (Fig. 5). The high favorability index zones for gold mineralization were found in the alteration zones corresponded to the fault intersections.

In another case study for gold prospecting in the Astaneh granite intrusive, West Central Iran, MPM was produced by

fusion of ASTER alteration maps, geochemical anomaly maps, and structural and lithology maps using the FLM (Moradpour et al. 2021). Table 3 shows the fuzzification parameters for the input layers applied in this analysis. The MPM indicated several high prospective zones in the study area. Most of the potential zones are situated in the central and southeastern parts of the study area. Such zones are associated with granitic intrusive and contact metamorphic rocks.

Application of Iterative Fuzzy Edge Detection Algorithm to Blurred Satellite Images

Several natural phenomena, including atmospheric effects, aerosols, fog, and clouds and their shadows, may reduce the contrast of satellite imagery. Therefore, edge detection algorithms are applied extract the edge of such degradation effects undesirably. Application of such algorithms is complicated, and using methods based on fuzzy logic can be helpful. In this regard, Rahimzadegan and Sadeghi (2016) applied an iterative fuzzy edge detection (IFED) algorithm to blurred remote sensing images. The IFED method was firstly introduced by Farbiz et al. (1998), which is implemented in two steps, including image enhancement and edge detection. The

Fuzzy Set Theory in Geosciences, Fig. 6 The used (a) fuzzy rules and membership functions and (b) membership functions based on the fuzzy logic. (Modified from Farbiz et al. 1998 and Rahimzadegan and Sadeghi 2016)

IFED algorithm applies an iterative process based on the fuzzy if-then-else method, initially introduced by Russo and Ramponi (1994) (Fig. 6). The steps of the proposed IFED algorithm are introduced as follows.

Initially the gray values (x_i) are mapped to the range of -256 to 256 . A $N \times N$ window is utilized to calculate the difference between x_i and its neighboring pixels. At the next step, membership functions are calculated based on Fig. 6, and the activity value of the membership functions are acquired. Then, y , the value to add to the pixel at the center of the window to acquire the enhanced gray level is calculated using the correlation-product inference mechanism. The enhanced gray values are computed by adding y to the gray value of the pixel at the center of the selected window. An iteration number with the least edge gray-value rate (EGR) is selected as the best number of the iterations to enhance the selected image. The EGR is calculated using the ratio of the

sum of the gray values in the 10% of higher and lower gray levels of the image. Afterwards, the edges of the regarding image are detected using “min” operator (Russo and Ramponi 1996). In the end, the produced gray value fuzzy edge image is binarized using “mean,” and then a crisp edge image is produced. To evaluate the IFED algorithm, the peak signal-to-noise ratio (PSNR) is utilized.

Three satellite sub-images of the Ikonos, Landsat 7, and SPOT 5 blurred by lowering atmospheric effects were studied in this research. A selected Ikonos sub-image (1 m spatial resolution) covered by a cloud was selected for the first test (Fig. 7a). The edges of the existing roads as the desired edges were extracted using IFED algorithm, while the edges of the clouds were ignored (Fig. 7a). Hence, due to the application of the fuzzy logic, IFED is able to detect the edges of the regarding features of land and ignore atmospheric contamination.

Fuzzy Set Theory in Geosciences, Fig. 7 Original images and results of the IFED algorithm for the sub-images of (a) Ikonos, (b) SPOT 5, and (c) Landsat 7. (Modified from Rahimzadegan and Sadeghi 2016)

A SPOT 5 sub-image (spatial resolution of 2.5 m) was selected as the second case study (Fig. 7b). The clarity of the selected sub-image was lowered by cloud and its shadow. The IFED algorithm can refuse detecting the edges of the cloud and the regrading shadow and extract the edges of the roads, even those are covered by the thin cloud (Fig. 7b).

A sub-image of Landsat (approximately 15 m spatial resolution) acquired over the sea, and its beach was used for the third investigation (Fig. 7c). As sea currents produce pixels with gray values different from the pixels of the sea, which may be detected by edge detection algorithms undesirably, the performance of the IFED algorithm can be evaluated in these areas. As demonstrated in Fig. 7C, the IFED algorithm ignores the undesired edges in the image, including the edges of the currents of the sea, and the desired edges such as the land features are detected clearly. Hence, IFED represented a good performance for the regions of the beaches and ignored undesired edges.

In general, the IFED method represents a significant performance to detect the desired edges of the blurred satellite images, including contaminations of natural phenomena such as sea currents, clouds and their shadows, land features in coastal waters, and fogs and smokes. Moreover, the IFED method can extract the edges of the desired land features, including farms, shorelines, roads, and buildings, efficiently. Such methods developed based on the fuzzy logic are appropriate to enhance blurred satellite images and extract the considered edges, which may include numerous uncertainty sources.

Summary or Conclusions

Given that most geospatial processes are vague and ill-defined, and the variables of the processes are poorly constrained, the fuzzy set theory provides a robust mathematical framework for modeling and predicting these processes. The functionality of all the three components, namely, the fuzzifier, the inference engine, and the defuzzifier, is equally important for the successful implementation of a fuzzy model. The fuzzifier, that is, the fuzzy membership function should simulate the human cognition for the efficient fuzzification of the input geospatial variables. It should be tuned to account for stochastic and systemic uncertainties in the geospatial datasets. The design of the inference engine should capture the subtle relationships between the variables of the geospatial process being modeled. The defuzzifier should return a crisp output that can be used for geospatial decision-making.

Genetic Algorithms

D. Arun Kumar

Department of Electronics and Communication Engineering and Center for Research and Innovation, KSRM College of Engineering, Kadapa, Andhra Pradesh, India

Definition

Genetic algorithms (GAs) are techniques with randomized solution search approach that obtain optimum solution using principles and parallelism of evolution and natural genetics. GAs obtain the optimal solution for complex problems using the fitness function. The implementation of GAs involves important steps, namely, a selection of the population, evaluation of fitness, defining crossover, mutation, and convergence to the optimal solution.

Introduction

The advancement of sensor technology has generated a large amount of data. There exist various types of data analysis methods such as data classification, data clustering, and regression (Duda et al. 2000). In data classification, the input data sample is classified into a specific class based on its feature values. The input sample is assigned to a specific class (Theodoridis and Koutroumbas 1999). In data clustering, the input data samples are grouped based on their feature values. In regression, the continuous values of output variable are predicted using linear or non-linear models (Duda et al. 2000).

There exist various mathematical models such as random forests, decision trees, and support vector machines (SVMs) that are used to analyze the data. In this direction, GAs are widely used in data analysis methods. GAs are used in optimization problems such as data classification, clustering, and

regression analysis. The advantage of GAs, such as the ability to find optimal solutions in complex, large, and multimodal search space, is the reason for their utilization in data analysis.

The implementation of GAs for data analysis is inspired by the natural genetics and evolution processes. The implementation steps of GAs are given in Fig. 1.
